Critical Care

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Critical Care

Edited by

John M. Oropello, MD, FACP, FCCP, FCCM

Professor of Surgery & Medicine

Program Director, Critical Care Medicine

Co-Director, Surgical ICU

Icahn School of Medicine at Mount Sinai

New York, New York

Stephen M. Pastores, MD, FACP, FCCP, FCCM

Professor of Medicine and Anesthesiology

Weill Cornell Medical College of Cornell University

Program Director, Critical Care Medicine

Department of Anesthesiology and Critical Care Medicine

Memorial Sloan Kettering Cancer Center

New York, New York

Vladimir Kvetan, MD

Director

Jay B. Langner Critical Care System

Professor of Anesthesiology & Clinical Medicine

Associate Professor of Surgery

Montefiore Medical Center

Albert Einstein College of Medicine

Bronx, New York

New York Chicago San Francisco Athens London Madrid Mexico City
Milan New Delhi Singapore Sydney Toronto

McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

We dedicate this 1st edition of Lange Critical Care to:

Our families:

Hiromi, Adrianna, and Luke Oropello

Cindy Conley and Henry Kvetan

Maria Teresa DeSancho, MD, MSc, Steven Michael, and Monica Cristina Pastores

For their love and understanding

and

To Our Critical Care Fellows, past, present, and future

and

To the generations of intensivists whose selfless clinical and academic work will change
the face of our chosen specialty for our patients, as well as advance the governance of
critical care with the leadership of our institutions.

Contents

Contributors xiii

Preface xxiv

SECTION

I

Pre-ICU Critical Care

- 1** Triage and Transport in the Field for the Critically Ill Patient 1
Carla Venegas-Borsellino, MD
- 2** Resuscitation and Stabilization 13
Daniel J. Singer, MD; Scott Weingart, MD, FCCM and Reuben J. Strayer, MD, FRCPC, FAAEM
- 3** Targeted Temperature Management After Cardiac Arrest 29
Oren A. Friedman, MD
- 4** Military-Related Injuries 41
Jamie M. Rand, MD, FACS and Aditya Uppalapati, MD
- 5** Regionalization 53
Christopher W. Seymour, MD, MSc and Jeremy M. Kahn, MD, MSc
- 6** Pre-ICU Syndromes 63
George Lominadze, MD; Massoud G. Kazzi, MD and Ariel L. Shiloh, MD
- 7** Biomarkers in Decision Making 73
Anthony Manasia, MD and Jon Narimasu, MD
- 8** Controversies in Therapeutic Hypothermia 83
Jose R. Yunen, MD and Rafael Tolentino, MD

SECTION

II

ICU Critical Care

- 9** Bedside Technology 91
Tara T. Bellamkonda, DO; Victor Murgolo, CCRN and John M. Oropello, MD, FACP, FCCP, FCCM
- 10** Physical Examination in the ICU 101
Ella Illuzzi, RN, ANP-BC and Mark Gillespie, PA-C, MS
- 11** Imaging of the Critically Ill Patient: Radiology 111
Nida Qadir, MD and Roshen Mathew, MD
- 12** Imaging the Critically Ill: Bedside Ultrasound 137
Alfredo Lee Chang, MD; Lewis Ari Eisen, MD and Marjan Rahmanian, MD
- 13** Patient Safety in the ICU 153
Jason Adelman, MD, MS
- 14** ICU-Acquired Weakness and Early Mobilization in the Intensive Care Unit 161
Carol Hodgson, PhD, FACP and Eddy Fan, MD, PhD
- 15** Pharmacology in Critical Illness 177
Julie Chen, PharmD, BCPS and Adam Keene, MD
- 16** Analgesia, Sedation, and Neuromuscular Blockade 189
Erik Stoltenberg, MD and Aaron M. Joffe, DO, FCCM

- 17** Airway Management/The Difficult Airway 203
Venketraman Sahasranaman, MD;
Tarang Sati, MD; Mabel Chung, MD and
Jay Berger, MD/PhD
- 18** Ventilator Technology and Management 221
Adebayo Esan, MBBS, FCCP, FACP; Felix Khusid
RRT- ACCS, NPS, RPFT, FAARC, FCCM, FCCP and
Suha il Raoof, MD, FCCP, MACP, CCM
- 19** The Acute Respiratory Distress Syndrome 249
Emily Fish, MD, MPH and
Daniel Talmor, MD, MPH
- 20** Venous Thromboembolism 257
Erica Bang, MD and Stephen M. Pastores, MD,
FACP, FCCP, FCCM
- 21** Shock: Diagnosis and Management 267
Kevin C. Doerschug MD, MS, FCCP and
Gregory A. Schmidt, MD, FCCP
- 22** CPR and ACLS Updates 277
Carla Venegas-Borsellino, MD and
Maneesha D. Bangar, MD
- 23** Arrhythmia Diagnosis and Management 289
Dipti Gupta, MD, MPH and Nancy Roistacher, MD
- 24** Acute Cardiac Ischemia 303
Matthew I. Tomey, MD and
Umesh K. Gidwani, MD
- 25** Heart Failure Syndromes in the Critical Care Setting 317
Omar Saeed, MD and James M. Tauras, MD
- 26** Pulmonary Arterial Hypertension in the ICU 325
Noam Broder, MD and Ronald Zolty, MD, PhD
- 27** Electrolyte Disorders in Critically Ill Patients 335
Sheron Latcha, MD, FASN
- 28** Acid-Base Disorders 349
James A. Kruse, MD
- 29** Nutrition Support 361
Ylaine Rose T. Aldeguer, MD;
Sara Wilson, MS, RD, CNSC and
Roopa Kohli-Seth, MD
- 30** Acute Kidney Injury and Failure 375
Pritul Patel, MD and Leila Hosseinian, MD
- 31** Renal Replacement Therapy 385
George Coritsidis, MD and Saad Bhatti, MD
- 32** Hematologic Dysfunction in the ICU 401
John C. Chapin, MD and
Maria T. Desancho, MD, MSc
- 33** Transfusion Medicine in Critical Care 417
Aryeh Shander, MD; Carmine Gianatiempo, MD
and Lawrence T. Goodnough, MD
- 34** Anticoagulation 429
Victor F. Tapson, MD and Shant Shirvanian, MD
- 35** Acute Abdominal Dysfunction 443
Vanessa P. Ho, MD, MPH and
Philip S. Barie, MD, MBA, FIDSA, FCCM, FACS
- 36** Gastrointestinal Hemorrhage (Upper and Lower) 457
Pari Shah, MD, MSCE
- 37** Liver Failure: Acute and Chronic 469
Brian Kim, MD and Leona Kim-Schluger, MD
- 38** Fever in the ICU 481
Anuja Pradhan, MD and Daniel Caplivski, MD
- 39** Community-Acquired Infections in the ICU 489
Meenakshi M. Rana, MD
- 40** Health Care–Associated Infections 503
Subani Chandra, MD and David Chong, MD
- 41** HIV Infection in Critically Ill Patients 515
Mekeleya Yimen, MD

- 42** Sepsis, Septic Shock, and Multiple Organ Failure 525
Russell J. McCulloh, MD and Steven M. Opal, MD
- 43** Antimicrobials in the ICU 539
Perminder Gulani, MD; Julie Chen, PharmD, BCPS; and Adam Keene, MD, MS
- 44** Endocrine Dysfunction Leading to Critical Illness 551
Michael A. Via, MD and Jeffrey I. Mechanick, MD
- 45** Oncologic Emergencies 563
Cristina Gutierrez, MD and Stephen M. Pastores, MD, FACP, FCCP, FCCM
- 46** Rheumatologic and Inflammatory Conditions in the ICU 573
Deborah Orsi, MD; Wilma Correa-Lopez, MD and John Cavagnaro, PA
- 47** Skin Complications 585
Bonnie Koo, MD; John K. Nia, MD and Annette Czernik, MD
- 48A** Principles of Neurosciences Critical Care 599
Christopher Zammit, MD; Ko Eun Choi, MD and Axel Rosengart, MD, PhD, MPH
- 48B** Critical Care of Cerebrovascular Disease 625
Christopher Zammit, MD; Ko Eun Choi, MD and Axel Rosengart, MD, PhD, MPH
- 49** Delirium in the Intensive Care Unit 645
S. Jean Hsieh, MD
- 50** Traumatic Brain and Spinal Cord Injury 659
Vikram Dhawan, MD and Jamie S. Ullman, MD, FACS, FAANS
- 51** General Postoperative Management 675
Leon Boudourakis, MD, MHS and Adel Bassily-Marcus, MD
- 52** Posttransplantation Care 685
Pankaj Kapadia, MD and John M. Oropello, MD, FACP, FCCP, FCCM
- 53** Posttrauma Care 695
J. David Roccaforte, MD
- 54** Postcardiothoracic Surgery Care 709
Mabel Chung, MD and Anthony Carlese, DO
- 55** Postoperative Management After Specialty Surgery 729
Nagendra Y. Madisi, MD and John M. Oropello, MD, FACP, FCCP, FCCM
- 56** Postoperative Vascular Surgery Care 739
Charanya Sivaramakrishnan, MD and Rami Tadros, MD
- 57A** Smoke Exposure Models in COPD 753
Patrick Geraghty, PhD and Robert Foronjy, MD
- 57B** Toxic Pulmonary Inhalation 771
Jennifer Wang, DO and John M. Oropello, MD, FACP, FCCP, FCCM
- 58** Overdose, Poisoning, and Withdrawal 777
Edward Mossop, MD and Fred DiBlasio, MD
- 59** Environmental Injuries and Toxic Exposures 813
Zaffar K. Haque and Tihomir Stefanec
- 60** Critical Care Issues in Pregnancy 829
Alina Dulu, MD; Ellie S. Ragsdale, MD and Dena Goffman, MD
- 61** Critical Care of Burn Patients 851
Edward Pellerano Guzman, MD and John M. Oropello, MD, FACP, FCCP, FCCM
- 62** Critical Care of Disaster Victims 861
Carla Venegas-Borsellino, MD; Sharon Leung, MD, MS and Vladimir Kvetan, MD
- 63** Controversies: Scoring Systems in Critical Care 873
Michael Elias, MD and John M. Oropello, MD, FACP, FCCP, FCCM
- 64** Controversies: Patient-Controlled Sedation—Ready for Prime Time? 879
Annie Lynn Penaco, MD and Jay Berger, MD/PhD

- 65** Ventilator Weaning—Which Strategy Is Better? RT-RN Versus Physician Driven 887
Ilde Manuel Lee, MD and Louis P. Voigt, MD
- 66** Controversies: Invasive Versus Noninvasive Strategy for Diagnosing Respiratory Failure 895
Anil Singh, MD and
Stephen M. Pastores, MD, FACP, FCCP, FCCM
- 67** “Controversies: Ventilator Management in ARDS: One Size Fits All?” 903
Muhammad Adrish, MD and
Graciela J. Soto, MD, MS
- 68** Controversies: Corticosteroids for ARDS: Friend or Foe? 911
Paul E. Marik, MD, FCCM, FCCP
- 69** Thrombolytic Therapy for Submassive Pulmonary Embolism 919
Samarth Beri, MD and
Stephen M. Pastores, MD, FACP, FCCP, FCCM
- 70** Controversies: Enteral Nutrition—Pyloric Versus Postpyloric 925
Amar Anantdeep Singh Sarao and
Roopa Kohli-Seth
- 71** Controversies: Continuous Versus Intermittent Renal Replacement in the Critically Ill Patient 931
Min Jung Kim, MD and John M. Oropello, MD, FACP, FCCP, FCCM
- 72** Clinical Controversies: Ventilator-Associated Pneumonia: Does It Exist? 941
Kaye Hale, MD
- 73** Controversies: Scvo₂ Versus Lactate Clearance to Guide Resuscitation in Septic Shock? 947
Jan Bakker, MD, PhD, FCCP
- 74** Controversies: Is Glucose Control Relevant? 957
Adel Bassily-Marcus, MD and Inga Khachaturova, MD

SECTION

III

Management

- 75** Simulation and Education in the ICU 961
Maneesha Bangar, MD; Carla Venegas-Borsellino, MD and Lewis A. Eisen, MD
- 76** ICU Bed Utilization 971
Hannah Wunsch, MD, MSc
- 77** The ICU in the Global Hospital Environment 977
Hayley B. Gershengorn, MD
- 78** Alternative Staffing Models in the ICU 985
Jibran Majeed, ACNP-BC, CCRN;
David Keith, PA-C, MS and
Rhonda D’Agostino, ACNP-BC, FCCM
- 79** Governance 995
Stephen M. Pastores, MD, FACP, FCCP, FCCM and
Vladimir Kvetan, MD, FCCM
- 80** Managing the ICU From Afar: Telemedicine 1001
Tzvi Neuman, DO and Baruch Goldstein, MD
- 81** Ethics and Palliative Care in the Intensive Care Unit 1009
Aluko A. Hope, MD, MSCE
- 82** Intensive Talk: Delivering Bad News and Setting Goals of Care 1021
Dana Lustbader, MD and Negin Hajizadeh, MD
- 83** Can Intensivist Performance Be Measured? 1029
Sharon Leung, MD, MS, FCCP
- 84** Complications: Never Never or Never Ever 1035
Ef e Singas, MD and Dana Lustbader, MD
- 85** Controversies: Noninvasive Ventilation at the End-of-Life—Useful or Not? 1041
Katerina Rusinova, MD; Alexandre Demoule, MD and Elie Azoulay, MD

SECTION
IV

Post-ICU Critical Care

- 86** Post-Intensive Care Syndrome 1045
Leonard Lim, MD and Graciela Soto, MD, MS
- 87** Outcomes Research and Reporting 1055
Angela K. M. Lipshutz, MD, MPH and
Michael A. Gropper, MD, PhD

SECTION
V

Genomics of Critical Care

- 88** Critical Care Medicine in the Era of
Omics 1067
Samantha Strickler, DO and John M. Oropello,
MD, FACP, FCCP, FCCM

SECTION
VI

Critical Care Procedures

- 89** Arterial Line Monitoring
and Placement 1085
Richard Weiner, MSN, RN, ANP-BC; Erin Ryan, RN,
NP and Joanna Yohannes-Tomicich, MSN, RN, NP-C
- 90** Bronchoscopy 1093
Preethi Rajan, MD and
Sanjay Chawla, MD, FACP, FCCP, FCCM
- 91** Cardiac Output Measurement 1099
Paul E. Marik, MD, FCCM, FCCP
- 92** Cardioversion and Defibrillation 1111
Rohit R. Gupta, MD and Ylaine Rose T. Aldeguez, MD
- 93** Central Venous Access 1121
Amit Pandit, MD; Leon Chen, MSc, AGACNP-BC,
CCRN, CEN and Daniel Miller, MD
- 94** Chest Tube Insertion 1131
Lewis Eisen, MD

- 95** Critical Care Echocardiography 1141
Yonatan Y. Greenstein, MD and
Paul H. Mayo, MD, FCCP
- 96** Extracorporeal Membrane
Oxygenation 1151
Muhammad Adrish, MD; Sharon Leung, MD, MS;
William Jakobleff, MD and Anthony Carlese, DO
- 97** Airway Management in the Critically Ill
Patient 1159
Elvis Umanzor, MD and Andrew Leibowitz, MD
- 98** Endoscopic Placement of Feeding
Tubes 1169
Isaac Soo, MD and Mark Schattner, MD
- 99** Continuous Venovenous
Hemofiltration 1177
Anthony Manasia, MD, FCCP and
Renzo H. Hidalgo, MD
- 100** High-Frequency
Oscillatory Ventilation 1185
Michael Duff, MD and Stephen M. Pastores, MD,
FACP, FCCP, FCCM
- 101** Intracranial Pressure Monitoring 1189
Nelson Moussazadeh, MD; Philip E. Stieg, PhD, MD
and Halinder S. Mangat, MD
- 102** Lumbar Puncture 1197
Mai O. Colvin, MD; Ariel L. Shiloh, MD and
Lewis A. Eisen, MD
- 103** Temporary Pacemaker Insertion and
Management of CV Implantable Electrical
Devices in the ICU 1207
Michael J. Grushko, MD and Jay N. Gross, MD
- 104** Paracentesis 1215
Claude Killu, MD and Mark Ault, MD
- 105** Percutaneous Tracheostomy 1225
Robert Lee, MD and Mohit Chawla, MD, FCCP
- 106** Pericardiocentesis 1233
Martin E. Goldman, MD

- 107** Pulmonary Artery Catheterization 1245
Rafael Alba Yunen, MD and John M. Oropello, MD,
FACP, FCCP, FCCM
- 108** Thoracentesis 1263
Satish Kalanjeri, MD and Stephen M. Pastores, MD,
FACP, FCCP, FCCM
- 109** Controversies: Early Tracheotomy 1271
Bradley A. Schiff

SECTION

VII

Appendices

- 110** Antimicrobial Prophylaxis
for Surgery 1277
Jun Makino, MD and John M. Oropello, MD, FACP,
FCCP, FCCM
- 111** Units and Conversions 1285
Jun Makino, MD and John M. Oropello, MD, FACP,
FCCP, FCCM

- 112** Medication Dosing During Renal
Replacement Therapy 1289
Jun Makino, MD and John M. Oropello, MD, FACP,
FCCP, FCCM
- 113** Drugs in Pregnancy 1313
Natalie Kostecky, RN, BSN and
Stephen M. Pastores, MD, FACP, FCCP, FCCM
- 114** Formulas 1317
Natalie Kostecky, RN, BSN and
Stephen M. Pastores, MD, FACP, FCCP, FCCM
- 115** Algorithms for Resuscitation 1321
Natalie Kostecky, RN, BSN and
Stephen M. Pastores, MD, FACP, FCCP, FCCM
- 116** Bedside Statistical Tools 1331
John T. Doucette, PhD and Steven Krasnica, MD
- Index 1339

Preface

We present Lange Critical Care in the spirit of our philosophy that the distinctions between critical care medicine, critical care surgery, and critical care anesthesiology are artificial; more the result of politics than medicine. All intensivists, regardless of primary discipline, must possess a core set of critical care skills that allow them to manage the sickest of patients. Surgical, medical, anesthesia, or neurological problems can arise in any patient, particularly in the critically ill. Furthermore, most hospitals today contain intensive care units (ICUs) that are mixed by intention or by overflow and multidisciplinary trained intensivists are best equipped to both recognize and manage the wide range of acute care problems.

The chapters reflect the growing scope of critical care provided outside of the ICU and the increasing importance and recognition of critical care services within the hospital structure. The Pre-ICU Critical Care section focuses on triage, transport, resuscitation, and stabilization, and includes forward-looking chapters on pre-ICU syndromes, hypothermia, military-related injuries, regionalization of critical care, and biomarkers in decision making. The second and largest section, ICU Critical Care, contains over 74 chapters and subchapters on multidisciplinary critical care that includes comprehensive coverage of medical, surgical, anesthetic, and neurological issues involving multiple organ systems. The third section, Management, includes chapters on education and simulation, bed utilization, the ICU's role in the global hospital environment, ICU staffing models, telemedicine issues, ethics, palliative care, and ICU governance. The fourth section, Post-ICU

Critical Care, contains chapters on postintensive care syndrome and outcomes research. The fifth section, Genomics of Critical Care, contains one chapter, Critical Care Medicine in the Era of Omics, written to provide a basic understanding of the potential applications of genomics unique to tackling critical illnesses. An integral part of critical care practice is addressed in the sixth section, Critical Care Procedures, that includes guidance in maintaining patient safety and extracting accurate information from monitors. The seventh section, Appendices, contains reference material and formulas, including a chapter on bedside statistics, an essential skillset for the modern intensivist. Sprinkled throughout each section are “Controversies” chapters provided to address some of the more ambiguous aspects of critical care.

In keeping with the team approach and multi-professional nature of critical care delivery, several chapters are authored or coauthored with critical care fellows, ICU nurses, physician assistants, nurse practitioners, and pharmacists.

In addition to practicing critical care physicians and fellows in training, this edition is designed to be a valuable resource for all critical care providers—hospitalists, subspecialty physicians, residents, nurses, physician assistants, nurse practitioners, nutritionists, pharmacists, respiratory therapists, and medical students.

We are grateful to the publishing editors at McGraw-Hill (Brian Belval, Christie Naglieri, and Kathryn Schell) for their tireless efforts and guidance in the production of this textbook.

Triage and Transport in the Field for the Critically Ill Patient

1

Carla Venegas-Borsellino, MD

KEY POINTS

- 1 The combination of an increasing patient population and diminished funding for hospital services is creating a need for optimized distribution of medical resources. Efficient management of major incidents involves triage, treatment and transport.
- 2 Triage tools would benefit initial allocation and future allocation of resources over time to support ongoing needs of survivors of critical illness. Over triage might overburden the local health care systems, have a negative impact on patient outcomes, and decrease cost effectiveness.
- 3 This is a review of the most common triage protocols used for illness scoring as methods to identify the severity of the injury, and the most often recommended guidelines for field triage of injured patients.
- 4 Critical care regionalization is becoming more common and studies have supported that the transport of critically ill patients to a tertiary care center leads to better patient outcomes.
- 5 Patients' and providers' safety, as well as the benefits and cost-effectiveness of the mode of transport are key considerations when assessing whether to transport a critically ill patient. Current standards for interfacility transport dictate that the decision on transport mode and team composition is based on individual patient requirements, considering minimization of transport time and anticipated treatment requirements during transport.

INTRODUCTION

The word “triage” originates from the French “trier” (to choose from among several) and was originally applied around 1792 by Baron Dominique Jean Larrey, surgeon-in-chief to Napoleon’s Imperial Guard, in reference to the process of sorting wounded soldiers. Its aim was to optimize the use of available medical resources to maximize efficacy; patients with the greatest chance of survival and the least

resource use are treated first.¹ Currently, the combination of an increasing patient population and diminished funding for hospital services is creating a need for optimized distribution of medical resources. Efficient management of major incidents involves triage, treatment, and transport. Useful triage tools would predict which patients have the greatest chance of survival, which patients are likely to die, and which will benefit most from advanced

medical care such as mechanical ventilation. These are important issues not only for initial allocation of resources but also for future allocation of resources over time to support the ongoing needs of survivors of critical illness.

The challenges associated with the triaging process have caused health systems to initiate a number of adaptational strategies, including regionalization of care, specialization of critical care facilities, and better allocation of available personnel and equipment; the triaging process impacts multiple practices such as pre-hospital care, emergency department services, intensive care, surgical intervention, and the process of determining the order of rank for patients to receive advanced therapeutic treatments (including renal replacement therapy and organ transplantation). In the field, emergency medical services (EMS) providers must ensure that patients receive prompt and appropriate emergency care and are transported in a timely manner to a health care facility for further evaluation and treatment. Identifying the severity of the injury or illness, prioritizing medical management, and determining the appropriate facility to which a patient should be transported can have a profound impact on subsequent morbidity and mortality.²

It is well described that overtriage might overburden the local health care systems, have a negative impact on patient outcomes, and decrease cost-effectiveness. Frykberg and Tepas³ in their published experience with terrorist bombings found a mean over triage rate of 59% and identified a linear relationship between overtriage rate and critical mortality. However, being too selective might lead to unacceptably high rates of undertriage and also increased morbidity and mortality.⁴ Because poor triage quality may lead to adverse consequences and bring multiple ethical and legal questions, the process should be based on recommended (research-based) protocols and guidelines, and be clear, transparent, and consistent. Unfortunately, an extensive literature review published in 2013⁵ reported that even though there are some scoring systems available to evaluate the severity of injury, algorithms to guide the initial clinical management, and recommendations about where to transport injured patients, there is little documentation about the effectiveness of these strategies on clinical outcomes.

In this chapter, we review the most common triage protocols used for illness scoring as methods to identify the severity of the injury, and the most often recommended guidelines for field triage of injured patients, along with accompanying recommendations regarding transport of critically ill patients in the field.⁶

It is important to emphasize that these guidelines are based on anatomic, physiologic, and/or situational factors intended to be applicable to patients with major risk of injury and/or significant negative outcomes; however, in light of a relative dearth of evidence-based medicine support, such scores must be used with full appreciation of their limitations. Though the guidelines are useful for comparing institutional performances and outcomes in studies of certain groups of patients, great caution must be exercised when applying these protocols to individual patients.

EVIDENCE-BASED TRIAGE AND TRANSPORT OF THE CRITICALLY ILL PATIENT

In general, evidence-based guidelines focused on pre-hospital care are lacking. Beate Lidal et al⁵ conducted a systematic review of 120 publications to identify available research on the effects on health outcomes of validated triage systems used in the pre-hospital EMS, and found that none of the identified articles fulfilled their inclusion criteria or answered their scientific questions. They concluded that there is a lack of scientific documentation evaluating whether pre-hospital triage systems are effective, whether one triage system is more effective than others, and whether it is effective to use the same triage system in 2 or more settings of an EMS. This lack of validated efficacy was related to a gamut of important aspects of care: health outcomes, patient safety, patient satisfaction, user friendliness, resource use, goal achievement, and the quality of the information flow between the different settings of the EMS.

For medical transportation studies, the HEMS Manuscript⁷ is a draft in progress, developed by a multidisciplinary panel of experts on trauma funded by the National Highway Traffic Safety Administration, which attempts to develop guidelines

recommending an evidence-based strategy for the triage and transportation of all pre-hospital trauma patients who use 911 services. After an extensive literature review considering mortality, morbidity, and undertriage of critically ill patients as critical outcomes, the panel concluded 2 strong and 3 weak recommendations for (1) the mode of transport (Helicopter Emergency Medical Services [HEMS] vs Ground Emergency Medical Services [GEMS]), (2) the use of online medical control, and (3) considerations for local adaptation. All recommendations were supported only by low- or very-low-quality evidence. In their manuscript they recommend:

1. Triage criteria for all trauma patients should include anatomic, physiologic, and situational components to risk-stratify injury severity and guide decisions as to destination and transport modality. (Strong recommendation, low-quality evidence.)
2. EMS providers should not be required to consult with online medical direction (OLMD) before activating HEMS for trauma patients meeting appropriate physiologic and anatomic criteria for serious injury (Strong recommendation, low-quality evidence); for all other trauma patients, OLMD may be used to determine transportation method as long as it does not result in a significant delay. (Weak recommendation, very-low-quality evidence.)
3. HEMS should be used to transport patients meeting appropriate physiologic and anatomic criteria for serious injury to an appropriate trauma center if there will be a significant time savings over GEMS. (Weak recommendation, very-low-quality evidence.)
4. GEMS should be used to transport all other patients to an appropriate hospital, so long as system factors do not preclude safe and timely transportation. (Weak recommendation, very low-quality evidence.)

In general, these recommendations consider the most seriously injured patients and their families to serve them with the most expedient transport possible to the hospital. Although none of the HEMS activation variables has been prospectively validated

in multicenter trials, and while the time and cost-effectiveness of HEMS remain disputable, the panel recommends that the most seriously injured patients should be transported by HEMS over GEMS.

TRIAGE SCORING SYSTEM

Triage protocols should only be initiated when it is apparent that resource deficits will occur across a broad geographical area despite efforts to expand or acquire additional capacity. Different triaging scorings have been developed to help providers in making the critical decisions necessary to increase the likelihood of favorable outcomes for patients. However, there is insufficient scientific documentation to decide whether triage scales are reproducible, and also whether the current triage scales differ concerning safety, reliability, and reproducibility, especially in the pre-hospital setting.⁸ Some of the most used triage scales are discussed as follows.

Field Triage Decision Scheme

In 1986, the American College of Surgeons developed the Field Triage Decision Scheme (called “Decision Scheme”),⁶ which serves as the basis for triage protocols for state and local EMS systems across the United States. The Decision Scheme is the most often recommended algorithm that guides EMS providers through a 4-step decision-making process to determine the most appropriate destination facility within the local trauma care system. Since its initial publication, the Decision Scheme has been revised multiple times, updated last in 2011.

The recommendations are based on physiologic, anatomic, mechanism of injury, or situational factors, where each of these categories includes at least some variables that are associated with risk of major injury and more severe outcomes. The algorithm is divided into a step-by-step approach as described in [Table 1–1](#).

Although decisions might be dictated by standing protocols, for patients meeting the criteria in step 4, OLMD should be consulted to determine the most appropriate facility to treat patients requiring special consideration. If patients do not meet criteria for triage to a trauma center in steps 1 through 4 of the Decision Scheme, EMS providers should use local protocols for transport without the need to

TABLE 1–1 The field triage decision scheme.

Step	Criteria	Recommendations
Step One-Physiologic Criteria: Identify critically injured patients measuring vital signs and assessing level of consciousness. (Sen 65%, ppv 42%, Spe 85%)	Any patient with: <ul style="list-style-type: none">• Glasgow ComaScale of < 14• Systolic blood pressure < 90 mm Hg• Respiratory rate of < 10 or > 29 bxm (< 20 in infant aged < 1 year)	These patients have potentially serious injuries and should be transported to the highest level trauma center (Level I, if available).
Step Two-Anatomic Criteria: Recognition of patients who might have a severe injury but do no meet physiologic parameters. Anatomic criteria alone has Sen 50% and PPVof 22%. Combining anatomic and physiologic criteria have Sen 80% and PPVof 27%	Patients with: <ul style="list-style-type: none">• Any penetrating injuries to head, neck, torso, and extremities proximal to elbow and knee• Two or more proximal long-bone fractures• Flail chest or pelvic fractures• Crushed, degloved, or mangled extremity• Amputation proximal to wrist and ankle• Open or depressed skull fracture• Paralysis	These patients might have a severe injury and need care at a high-level trauma center but do not meet physiologic criteria. They should be transported to the highest level trauma center available in the system, typically Level I or II.
Step Three-Mechanism of injury Criteria: Apatient who does not meet Step One or Step Two criteria might still have severe, but occult injury. The mechanism of injury should be evaluated next to determine whether the injured person should be transported to a trauma center.	Transport to a trauma center if: <ul style="list-style-type: none">• Adults: fall > 20 feet, children aged < 15 years: fall > 10 feet or two to three times child’s height• High-risk auto crash; intrusion > 12”to the occupant site or > 18”to any site ejection from automobile, death in same passenger compartment; vehicle telemetry data consistent with high risk of injury; autoversus pedestrian/bicyclist thrown: run over, or with significant (> 20 mph) impact• Motorcycle crash > 20 mph.	These patients whose injuries meet mechanism-of-injury criteria but not physiologic or anatomic criteria should be transported to the closest appropriate trauma center, not necessarily to a center of ering the highest level of trauma care available.
Step Four-Special Considerations: Determining whether a patient who has not met the previous criteria has underlying conditions or comorbid factors that place him/her at higher risk for severe injury.	Include: <ul style="list-style-type: none">• Aged > 55 or < 15 years• On anticoagulation or bleeding disorders• Burns with trauma mechanism should be triage to trauma center; without other trauma mechanism should go to burn facility• Time-sensitive extremity injury• End-stage renal disease on HD• Pregnancy > 20 weeks• EMS provider judgment	These patients might require trauma-center care.

Data from Sasser SM, Hunt RC, Faul M, et al: Guidelines for field triage of injured patients: recommendations of the National Expert Panel on Field Triage, 2011, MMWR Recomm Rep. 2012 Jan 13;61(RR-1):1-20.

contact medical control. Owing to the complexity of traumatic injury and its evaluation, the last line of the Decision Scheme, essentially unchanged from previous versions, is “When in doubt, transport to a trauma center.”

The Sequential Organ Failure Assessment and Modified SOFA

The Sequential Organ Failure Assessment (SOFA) score is a validated measure of organ failure over time

and a predictor of mortality in critically ill patients⁹ that has been incorporated into triage protocols for critical care in the event of an influenza pandemic or a mass influx of patients during a disaster.¹⁰ The SOFA score combines a clinical assessment of 2 organ systems (cardiovascular and central nervous) with laboratory measurements for evaluation of 4 other organ systems: respiratory, hematologic, liver, and renal. The SOFA score has been shown to reliably evaluate and quantify the degree of organ dysfunction present on admission to the intensive care unit (ICU) (initial

score) or developing during ICU stay. The maximum SOFA score reflects cumulative organ dysfunction that develops and correlates with mortality, whereas the mean score is a good prognostic indicator—predicting outcome throughout an ICU stay.⁹

As the SOFA score requires laboratory measurement of 4 parameters (creatinine, platelet count, partial pressure of arterial oxygen, and serum bilirubin), this scoring system may be impractical with constrained resources. Looking for an alternative, Grissom et al¹¹ proposed a modified SOFA (MSOFA) score that requires only 1 laboratory measurement (creatinine, which can be measured using a bedside point-of-care testing device), eliminates the platelet count, and replaces the other laboratory test results with clinical measurements: saturation of oxygen and jaundice. They evaluated the accuracy of both scores in 2 key areas: (1) ability to predict mortality and (2) ability to predict need for mechanical ventilation in critically ill patients after admission to the ICU. Findings were that for predicting mortality on days 1 and 3, the MSOFA and SOFA scores are equally accurate, but for predicting mortality at day 5 of ICU stay, the predictive accuracy for both was diminished.

Both scores are equivalent in predicting ongoing requirements for mechanical ventilation, but because both scores exclude the patients with more than 11 points, the system excluded about 94% of total patients in their cohort, but up to 40% of these excluded patients would survive in a setting where ample critical care resources were available. This illustrates that these scoring systems can only be 1 part of an overall system of triage.¹⁰ The overall triage process should be based on a consideration of scoring systems and the analysis of preexisting comorbidities; to successfully use limited resources to save lives, strategically excluding patients with high risk of mortality must be considered.

Simple Triage Scoring System

Initially during the influenza pandemic in 2009, the UK Department of Health recommended the SOFA score as part of a staged triage and treatment prioritization tool during the initial weeks of an overwhelming influenza pandemic and to prioritize admission to critical care beds.¹² Further

data analysis suggests that SOFA score may not be a good predictor of outcome in this cohort of patients, and had surge capacity been overwhelmed, it may have led to inappropriate limitation of therapy. Before the pandemic, in 2007 Talmor et al¹³ proposed the Simple Triage Scoring System (STSS) as a potential alternative tool in predicting mortality and optimizing the utilization of critical care resources during epidemics. It uses only vital signs and patient characteristics that are readily available at initial presentation (age, shock index [heart rate > blood pressure], respiratory rate, oxygen saturation, and altered mental state). In 2011 Adeniji and Cusack¹² reviewed the performance of the admission STSS and SOFA scoring systems as indicators of optimal utilization of hospital resources, and of mortality during the H1N1 infection; they found that the STSS accurately risk-stratified patients with this viral illness with regard to the need for admission to the ICU and for mechanical ventilation, suggesting that the STSS performs better in this population and overall would be a more appropriate early assessment triage rule.

Abbreviated Injury Scale, Injury Severity Score, and the New Injury Severity Score

The Abbreviated Injury Scale (AIS) ranks different injuries with a numerical score from 1 for minor injury to 6 for probably lethal/maximum injury. In 1974, the Injury Severity Score (ISS) was derived from AIS scores and it uses an ordinal scale (range: 1-75) that summarizes and takes account of the effect of multiple injuries.¹⁴ The ISS is calculated by assigning AIS scores to injuries in each of 6 body regions (head/neck, face, thorax, abdomen/visceral pelvis, bony pelvis/extremities, and external structures) and then adds the squares of the highest AIS scores in each of the 3 most severely injured body regions. Only the most severe injury in each body region is used in the score. If an AIS score of 6 is assigned to any body region, the maximal ISS of 75 is assigned. The ISS is an accepted method of determining the overall severity of injury and correlates with mortality, morbidity, and length of hospital stay, and it has been used to predict mortality and risk for postinjury multiple organ failure.¹⁴

In a more recent study developed in a level 1 university trauma center, the New Injury Severity Score (NISS) showed that 7.5% patients with discrepant scores (NISS > ISS) had longer hospital and ICU stay and higher mortality rate (all $P < .01$), suggesting that the NISS has better predictive power related with these outcomes.¹⁵

Trauma Score and Revised Trauma Score

Because of the increasing number of trauma patients admitted to critical care facilities, familiarity with trauma scales is important. The Trauma Score (TS) is based on the Glasgow Coma Scale (GCS), and on the status of the cardiovascular and respiratory systems, it assigns values to each parameter and the scores are summed to obtain the total TS, which ranges from 1 to 16. Mortality risk varies inversely with the TS.¹⁶

After an evaluation of the TS by the same author, it was found that it underestimates the importance of head injuries, so the Revised Trauma Score (RTS)¹⁷ was proposed. The RTS demonstrated substantially improved reliability in outcome predictions compared to the TS and yielded more accurate outcome predictions for patients with serious head injuries than the TS. Currently, the RTS is the most widely used physiologic trauma scoring tool.

CRAMS Scale

The Circulation, Respiration, Abdomen, Motor, Speech (CRAMS) scale is another trauma triage scale that is frequently used to decide which patients require triage to a trauma center. Patients with lower CRAMS scale scores would be expected to require critical care unit admission.¹⁸

TRANSPORT OF THE CRITICALLY ILL PATIENT

Critical care regionalization is becoming more common and studies have supported that the transport of critically ill patients to a tertiary care center leads to better patient outcomes.¹⁹ As a result, there is increased interfacility transport of critically ill patients and the need to develop

methods for transport of these patients using practices based on the best scientific and management evidence.

Composition of the Transport Team

There are no national data on overall transport volumes or team composition within transport systems. Published guidelines recommend that a minimum of 2 medically qualified people in addition to vehicle operators accompany a critically ill patient, but there are no standard recommendations regarding which patients may be transferred solely with paramedics, which patients require a nurse in attendance, and which patients require a physician in attendance.²⁰

While in urban areas ground transport is most common, in rural areas air transport is more often required because of the distances involved and the difficulties of road travel. In most settings, the emergency medical technician (EMT) is the highest-level care provider on the interfacility transport team, but for critical care transports, it is most often a physician, nurse, or paramedic; many critical care transport programs are using physicians who are still in training on board transport vehicles. However again, there is little information speaking to how the level of experience of the physicians affects outcome. Therefore, current standards for interfacility transport dictate that the decision on transport mode and team composition is based on individual patient requirements, considering minimization of transport time and anticipated treatment requirements during transport.

Medical Management during the Transport

After a literature review concerning medical management in the pre-hospital setting, Ryyänänen et al²¹ concluded that cardiopulmonary resuscitation and early defibrillation are essential for survival, but providing these interventions in the pre-hospital setting has not shown improved survival, so the data regarding their effectiveness are contradictory. Better documentation is available supporting a reduction in mortality in patients with myocardial infarction when pre-hospital thrombolytic treatment is provided. Regarding the trauma patient, it is accepted to provide basic life support (BLS) in the case of

penetrating trauma and in cases of short distance to a hospital, but in patients with severe head injuries, advance life support (ALS) provided by paramedics and intubation without anesthesia can even be harmful. There is also some evidence supporting use of ALS among patients with epileptic seizures as well as those with respiratory distress.

Managing Airway

Critical care transport often involves advanced airway management that includes establishment of an advanced airway with standard endotracheal tube or backup tools such as laryngeal mask, pharyngo-tracheal lumen tube, or needle cricothyrotomy with emergency transtracheal jet ventilation. In addition to advanced airway management, ALS transport crews should have equipment available for decompression of tension pneumothorax (ie, either needle or chest tube thoracostomy).²⁰

Mechanical ventilation of intubated patients during transport has been shown to be optimal in comparison with manual ventilation; therefore, several types of ventilators are available for the transport environment. Transport ventilators must be monitored continuously during transport as they are subject to problems such as power failure and disconnection. Pressure-controlled ventilators are used most commonly during transport, and in aircraft they must be adjusted for altitude changes. While providing mechanical ventilation, patients need continuous oximetry and end-tidal carbon dioxide monitoring, to identify clinically unrecognized hypoxia.²²

Hemodynamic Monitoring

Interfacility critical care transport requires continuous monitoring and clinical management of the patient throughout the transport environment.²² The transporting vehicle should have the necessary power converters for all equipment that could be needed, battery backup in case of electrical failure, and backup oxygen supply in case of vehicle breakdown. In cold climates, provision must be made for maintenance of a warm environment in case of vehicle failure. Transport monitor devices include devices for measuring electrocardiography (ECG), blood pressure, oxygen saturation, and, if necessary, end-tidal carbon dioxide level, pulmonary artery pressure, intra-arterial pressure, and intracranial pressure.²⁰

Defibrillation has been performed safely during flight, and its use does not interfere with other systems on helicopters and fixed-wing aircraft. Medications should be administered by an infusion pump throughout transport to ensure accurate dosing. Many small infusion pumps are available and can be reprogrammed rapidly to manage unstable patients. In addition, new portable intra-aortic balloon pumps and left-ventricular assist devices are available, and can be transported on most ambulances, helicopters, and airplanes.²²

Medication

Medication lists have been published for the management of the obstetric, neonatal, pediatric, and adult patients during transport.²⁰ Special medications may be required according to patient needs, and protocols should be prepared beforehand for the use of these medications on route. Some common pharmacologic practices include the use of paralytic agents to facilitate endotracheal intubation, and thrombolytic agents for acute cardiac and stroke patients, but in general their use is still controversial.

Intravascular Access

Intraosseous (IO) access is an accepted method for providing vascular access in the out-of-hospital critically ill patients when traditional intravenous access is difficult or impossible. Different IO techniques have been used showing overall success rates of 50% using the manual needle, 55% using the bone injection gun, and 96% using the EZ-IO.²³

Controversies in Management

Blood product transfusion during interfacility transport is controversial. It has been shown that in HEMS using flight nurses, the transfusion of blood can be performed safely and is feasible during transport,²⁴ but the use of blood product transfusions is still limited to the length of the transport during which crystalloid infusion alone will not stabilize a patient. Use of blood products during transport requires adherence to strict standard blood transfusion protocols, with blood administered by properly trained transport personnel.

Modes of Transport

Current options for mode of transport are the ground ambulance, either a helicopter or a fixed-wing aircraft, and watercraft.²⁰ In many urban centers, all options are available, and in more remote rural areas the airplane is essential. Factors that will influence the mode of transport include the distance and duration of transport, the diagnosis and complications that may arise during transport, the level of training and techniques the transporting personnel can provide, the urgency of access to tertiary care, and local weather conditions and geography. In the United States, helicopters are used frequently for the transportation of trauma patients; a 2007 overview estimated that 753 helicopters and 150 dedicated fixed-wing aircraft are in EMS.²⁵

Ground Ambulance

Ground ambulances have the advantage of rapid deployment, high mobility, and lower cost. However, patients and equipment are subject to significant deceleration and vibration forces.²⁰ Ground ambulance vehicles are usually most readily available and should be considered for transport distances of 30 miles or less. They are categorized as vehicles for BLS or ALS. BLS ambulances are most often staffed with 2 EMTs whereas ALS ambulances are staffed with a paramedic, nurse, or physician as the highest-level provider. Ground ambulances are limited by surface conditions or traffic congestion. All of them should have a backup equipment supply (ie, batteries or oxygen tanks), and ALS ambulances, particularly, must have the necessary outlets for managing ventilators or balloon pumps for interfacility critical transfers. The US Department of Transportation (DOT) has published standards that have been adopted by most states that relate to minimum ambulance configuration and equipment requirements.²⁶ Communication between the ground ambulance and the receiving facility or designated medical control center can be considered during transport.

Helicopter

Fixed-wing or rotary aeromedical transport may be necessary during disasters to extricate victims via air.²⁰ Helicopters should be considered for transports over distances of 30 to 150 miles. They travel

at ground speeds of 120 to 180 miles/h and often are dispatched from the receiving tertiary facility or urban area emergency service providers. The physical location of the helicopter at the time of dispatch is important to consider because an in-flight round trip to transport a patient may not offer advantages over a 1-way trip by an available ground vehicle. Helicopters usually require a warm-up time of 2 to 3 minutes before liftoff and, allowing for communication time, can be launched within 5 to 6 minutes of receipt of the flight request. Medical transport helicopters are usually staffed by critical care crews, and the number of patients who can be transported is determined by aircraft capacity. Under normal weather conditions, helicopters can fly point to point and land at accident scenes or sending facilities; the liftoff capability depends on the type of helicopter used. Helicopter transports are limited by adverse weather conditions and available landing sites (often a problem in densely populated areas).

Fixed-Wing Aircraft

Fixed-wing aircraft should be considered for transport over distances exceeding 100 to 150 miles. Being faster, they have the advantage of having a greater range and the ability to fly in difficult weather conditions, but they are limited by the need for ground transportation at both ends.²⁰ Though there is reduced noise, significant forces (fore/aft) are exerted on the patient and may affect critically ill patients who have a decreased physiologic reserve. Aircraft cabins are normally pressurized at altitudes between 6000 and 8000 ft, and this may have effects not only on the patient's clinical condition but also on medical devices.

Watercraft

Watercrafts are rarely used for interfacility critical care transport. However, in special environments, such as offshore islands and oil platforms, watercrafts play a role in medical transport.²⁰ Their use usually comes into play in situations where inclement weather does not allow for helicopter transport. Because of problems with water damage to electric equipment and dangers of staff electric shock from defibrillators, the monitoring and ALS activities that can be supported on watercraft are limited.

NEW CHALLENGES IN TRIAGE AND TRANSPORT OF CRITICALLY ILL PATIENTS

Critical care triage and transport are not uncommon practices; yet there is a relative lack of available comparative research studies that address (sometimes controversial) practices in this area of medicine because of the ethical implications of such studies, the nature of urgent and intensive care, and the large number of variables to consider.

Ethical Impact

When resource scarcities occur, ethical and international laws dictate that triage protocols should be used to guide resource allocation, and that they should equitably provide every person the “opportunity” to survive.²⁷ As this law does not guarantee either treatment or survival, performing triage of critical care services introduces several ethical challenges. To conscientiously meet these challenges, it is important to be familiar with the 4 principles of biomedical ethics developed by Beauchamp and Childress²⁸ and to understand their application to the critically ill patient.

Autonomy: Respect for autonomy is a fundamental criterion for decision making in health care and provides that competent persons have the right to make choices regarding their own health care.²⁸ In the critical care setting, autonomy is very difficult to assess due to the urgency of the situations, lack of privacy, and lack of an established medical relationship. For the health care provider, it is important to focus on good and clear communication, even when the informed consent is not part of triage procedure.

Beneficence: Beneficence is the moral obligation of contributing to the benefit or well-being of people, and thus is a positive action done for the benefit of others, rather than merely refraining from harmful acts.²⁸ By applying a system of triage, the health care provider strives to improve the quality of care by using the available resources as effectively and efficiently as possible. The ultimate goal of triage is to preserve and protect endangered

human lives as much as possible by assigning priority to patients with an immediate need for life-sustaining treatment. In triage, the tendency of overtriage, particularly in patients with trauma, may be a tendency for beneficence, to “err on the side of caution.” However, overtriage not only increases the cost of medical care but also may result in worse outcome.²⁹

Nonmaleficence: The principle of nonmaleficence can be described as “do no harm” and it is part of The Hippocratic Oath every health care provider commits to. Harm is not directly inflicted by triage except, perhaps when hopelessly injured patients are considered in the dead category.²⁸ Even during disasters, health care professionals are always obligated to reasonably provide the best care. So the aim of triage is to secure fair and equitable resources and protections for vulnerable groups. Triage guidelines aim to avoid harm to the patient by sorting the patients as quickly and efficiently as possible. However, in emergency care, especially in situations of overcrowding, treating one patient might indirectly threaten the welfare of another patient; any delay in treatment can potentially be harmful, but may be unavoidable if resources are limited. Our best efforts to use good communication skills and maximize allocation of resources can help us preserve principle of nonharming by reducing as much as possible any delay in treatment.

Justice: Distributive justice requires that, given limited resources, allocation decisions must be made fairly, and that the benefits and burdens are distributed in a just and fair way.²⁸ Triage schemes are designed to allocate the benefits of receiving health care among the injured persons, but it does not mean that each person will receive equality if there are scarce resources; this aspect makes the triage of critically ill patients especially challenging. The triage equity perspective should be based on 3 principles: (1) Principle of equality: Based on the idea that each person’s life is of equal

worth and everyone should have an equal chance to receive necessary care. But this does not imply that the triage system can simply operate on a first-come first-service basis, because in an emergency care scenario this is a suboptimal strategy. (2) Principle of utility: It considers providing the greatest good for the greatest number. To respect this principle, the triage system should allocate scarce medical resources as efficiently as possible, seeking to achieve survival, restoration or preservation of function, and minimize suffering. To maximize benefit at the macro level, bad consequences for some (at micro level) may be justified if an action produces the greatest overall benefit. (3) The principle of worst-off: This principle depends on how worst-off is defined; most likely in critical care it means the severely ill or injured patient with greatest risk of death. To consider this principle, triage systems would give priority to treat this sickest group, but when resources are scattered, this approach can be inefficient if maximizing the benefits for the close-to-death group of patients who are not likely to survive consumed resources that could have saved lives of those not as sick, but more likely to survive. Triage systems should focus on minimizing the number of avoidable deaths, directing resources to salvageable patients.

Most of the available literature related to triage focuses just on a medical perspective (clinically based guidelines recommendations) or an ethical perspective (with its conflicting principles). Aacharya et al²⁸ conducted a literature review, in an attempt to bring together these 2 strands of thought. They consolidated the results from the analysis, using the 4 principles of biomedical ethics, proposing a clinically integrated and ethically based framework of emergency department triage planning. After their review they concluded that emergency triage is a dynamic process that takes relevant ethical principles into account; as triage involves significant moral implications, public representatives and ethics scholars should participate in the development of ethically sound institutional policies on triage planning. As a dynamic process, triage planning

is a process susceptible to change and should be reviewed by multidisciplinary task forces and hospital ethics committees.

Safety

Safety of patients and EMS providers as well as the benefits and cost-effectiveness of the mode of transport are key considerations when assessing whether to transport a critically ill patient by ground or air, but the support regarding this topic is still controversial: One study has found no difference in transport times for HEMS versus GEMS³⁰; one found a positive, but not statistically significant, point estimate for the association between HEMS transport and scene trauma mortality³¹; and another, focused only on patients with severe injury as defined by ISS, found that transport by helicopter was associated with improved hospital-to-discharge outcomes, compared to ground transport.³² Methodologically, it is very difficult to evaluate the different transport modalities due to the influence of multiple variables such as local weather, traffic congestion, and EMS crew training. In general, the data indicate that the risks of aeromedical transport are very low, and the risk of ground transportation cannot be ignored.

Medical Legal Issues

Interfacility transport of patients has received increased legal attention especially regarding topics such as transfers of unstable patients, transfers of uninsured patients, and “antidumping legislation.”²⁰ Legally the sending facility is responsible for initiating the transfer, selecting the mode of transportation and the equipment on the transporting vehicle (including the level of expertise of transferring personnel), and ensuring that the receiving facility has space and personnel available for care of the patient. The sending physician is responsible for the risks of transfer and for deciding that the benefits to the patient following successful transfer outweigh the risks. A receiving facility that has specialized units shall not refuse to accept an appropriate transfer if that hospital has the capability to treat the individual. This is a nondiscrimination clause and is designed to

prevent receiving facilities from accepting only funded patients.

In addition, owing to the high degree of acuteness of these patients and potential for adverse outcomes, the resultant liability implications make it mandatory that transferring personnel have medical malpractice coverage.

Education and Training

A study has showed that training on triage skills using standardized simulated cases can decrease undertriage by 12%.³³ Training modules for all transporting personnel should be developed in such a way that it is consistent with the policies and practices of the local emergency medical services and critical care community. The facilities and the crew should be subjected to ongoing curriculum development and quality assurance by the medical director.

CONCLUSION

Triage, treatment, and transport of injured patients require careful attention to priorities, prevention of further injuries, and delivering reassurance and compassion to those who are injured. As mentioned by Pepe and Kvetan,³⁴ early treatment in the field should be focused on seriously injured persons who require immediate care but with a chance of survival. And most importantly, beyond the pre-hospital injury “management” or “treatment,” we should always provide the best possible pre-hospital care.

Critically ill patients generally require a high level of care during transport. Recommendations regarding transport of critically ill patients are supported by data that show that the critically ill patient has better outcomes in tertiary centers than in other facilities and that transport of the critically ill patient does not adversely affect the patient during transport and improves outcome when compared with national norms. Established systems of care (encompassing critical transport as a component) have societal outcomes better than those of comparable communities without such a system and better than those in the same community before the system was in place; regionalization of specialized care is cost-effective and improves utilization of community resources.

Even though conducting research in the pre-hospital environment and in EMS presents multiple challenges, there is a real need for more research specifically related to field triage recommendations, cost-effectiveness recommendations, how to improve trauma surveillance, and data systems able to analyze the impact of various policies and procedures affecting the care of acutely injured persons.

Resuscitation and Stabilization

2

Daniel J. Singer, MD; Scott Weingart, MD, FCCM and
Reuben J. Strayer, MD, FRCPC, FAAEM

KEY POINTS

- 1 The goal of the first 5 minutes of resuscitation is to establish conditions in which resuscitation can be effectively carried out, identify immediate life threats, and initiate stabilizing therapies.
- 2 Cardiac arrest must be recognized immediately, and may be missed in unresponsive or intubated patients unless specifically sought.
- 3 The four signs of airway embarrassment are change in voice, stridor, mishandling of secretions, and airway posturing.
- 4 Point-of-care sonography is indicated early in the management of all patients.
- 5 Blood pressure is the most basic proxy for tissue perfusion; however, a more reliable indicator of successful resuscitation is end-organ function.

Resuscitation—reanimation in many languages—is the restoration of life where it is absent or diminished. Resuscitation is the simultaneous identification and treatment of threats to life, limb, or function and is initiated by any qualified person whenever and wherever such a threat is recognized.

The need for resuscitation may announce itself with obvious signs such as a patient struggling to breathe or speak, by dramatic alterations in mental status, or by abnormal vital signs, but may also be manifested by more subtle markers of serious illness such as singed nasal hair, muffled voice, or a mottled extremity.

We will first describe a stepwise approach to the initial phase of resuscitation of the undifferentiated, critically ill patient—the primary survey—and then more comprehensively discuss the basic assessments, maneuvers, and strategies central to any resuscitation paradigm.

THE PRIMARY SURVEY

The goal of the first 5 minutes of resuscitation is to establish the conditions in which resuscitation can be effectively carried out, identify the most immediate life threats, and initiate stabilizing therapies ([Table 2–1](#)). The acronym used here is DC3A-J:

D: Danger

The first priority in resuscitation is to determine that it is safe to approach the patient; the first D stands for Danger—danger to the provider and the treatment team. This preliminary step assumes much greater importance in the prehospital environment than the operating theater, but all patients pose a potential threat to their treating clinicians. Scene security (from fire, armed aggressors, etc) is a clear priority in the field. In all settings, appropriate personal protective

equipment to shield against bloodborne or air-borne infectious disease is essential. Occasional patients will have a dangerous substance on their skin or clothes and require decontamination.

T e agitated patient deserves special consideration. In addition to the potential for violence against providers, which by itself would indicate appropriate chemical and physical restraint as an early priority, agitated patients can be broadly divided into two groups. In many cases, agitation can be confidently attributed to benign etiologies such as psychiatric disease or safe intoxicants; these patients can be managed in a measured, methodical fashion using de-escalation techniques or titrated chemical or physical restraints. Agitation, however, can either accompany or be caused by life-threatening disease, and in these cases the patient interfering with their care becomes an additional threat to their own safety. When sufficient concern for a dangerous condition exists, agitated patients must be immediately controlled using assertive doses of powerful

sedatives; we prefer ketamine, droperidol, and/or midazolam.¹

C: Call for help

Verify at the outset of care that the patient is in the appropriate location, and that the appropriate personnel and equipment are either at bedside or summoned. T is may mean activating emergency medical service (EMS), activating an in-house critical patient alert, or pushing the patient to another area in the department.

C: Calm

An important impediment to optimal patient care is apprehension and the resuscitator's own anxiety level should be actively managed. An early step to take in this regard is to make a loud room quiet. T is can be accomplished with a forceful quiet please and by requesting that observers not directly participating in patient care move to the perimeter or out of the room altogether. T is maneuver also establishes the resuscitation leader, which if not apparent should be done at this point.

In medical resuscitation, operator catecholamines generally rise in response to anxiety around the patient deteriorating despite efforts, or in anticipation of an infrequently performed procedure. An effective technique to combat this anxiety and lower catecholamines is to consider how the patient could deteriorate and decide, in as much detail as achievable, how to respond. Invisible simulation of this sort can be augmented if necessary by tactical breathing,¹ where relaxation physiology is harnessed to effect calm, which allows optimal decision making.

C: Cardiac arrest

Cardiac arrest must be recognized immediately, and may be missed in unresponsive or intubated patients unless specifically sought. In patients who are unresponsive to a painful stimulus and not certainly breathing (gasp-ing can occur in arrest or just prior to arrest) or intubated patients, the first consideration is

¹ One tactical breathing technique has the operator breathe in through the nose for 4 seconds, hold the breath for 4 seconds, exhale through the mouth for 4 seconds, then hold for 4 seconds. T is sequence is repeated 4 times.²

to establish the presence or absence of a pulse. This can be accomplished by palpation, a pulse oximetry waveform, or cardiac ultrasound.

As soon as pulselessness is detected, chest compressions are initiated, then the rhythm is established so that ventricular fibrillation and ventricular tachycardia may be defibrillated. While the search for the cause of arrest is ongoing, supportive therapies such as vasopressors and empiric treatment of relevant reversible causes of cardiac arrest are often provided; the establishment of vascular access is therefore an early priority in most scenarios, using an intraosseous cannula if venous access is not quickly obtained. This is the time to consider placing large-bore femoral cannulae if intra-arrest extracorporeal membrane oxygenation (ECMO) is available.

A: Airway

The goal of the airway assessment in the primary survey is to determine if an airway intervention is needed now or in the near term. Patients with dynamic airway lesions such as neck trauma, anaphylaxis, angioedema, and thermal or caustic inhalational injury demand a high level of vigilance and preparation for definitive airway management, even without signs of airway compromise. These bullets, bites and burns lesions can cause rapid deterioration of airway patency and escalation of difficulty in airway management. Otherwise, a patient who is able to speak comfortably with a clear voice is unlikely to require an immediate airway intervention.

The four signs of airway embarrassment are change in voice, stridor, mishandling of secretions, and airway posturing. Many patients who require resuscitation have decreased level of consciousness and demonstrate a patent, defended airway by handling their secretions: Drooling, gurgling, coughing, gagging, or sonorous respirations indicate the potential for an unprotected airway.

The airway interventions to consider in the primary survey include head and neck positioning (including jaw thrust), suctioning of oral secretions, removal of a foreign body,

placement of oral or nasal airways, placement of a laryngeal mask airway, or endotracheal intubation.

B: Breathing

The primary breathing assessment focuses on the adequacy of oxygenation and the provision of therapies to augment oxygenation when needed. In an alert patient, breathing competence is best assessed by respiratory effort; distress is indicated by high respiratory rate, recruitment of accessory muscles, and speaking in less than complete sentences. Pulse oximetry—especially room air pulse oximetry—is a reliable indicator of respiratory status in awake or obtunded patients, provided a good waveform is present. Auscultation of the lungs should be performed briefly, with the intent of identifying bilateral breath sounds, wheezes, and crackles.

Supplemental oxygen is the cardinal empiric therapy for breathing disorders. All critically ill patients should be placed on nasal cannula oxygen, which can be augmented with face mask oxygen or noninvasive ventilation (continuous positive airway pressure [CPAP]/bilevel positive airway pressure [BiPAP]) depending on the oxygenation deficit and its suspected etiology.

Other therapies to consider in the primary survey include nebulized albuterol for reactive airway disease, nitroglycerine for pulmonary edema, and thoracostomy (with needle, chest tube, or finger) for an unstable patient with pneumothorax. A portable chest radiograph may be called for when indicated.

C: Circulation

The initial assessment of circulation centers on the adequacy of organ perfusion, as evidenced by mentation and warm, dry skin with brisk capillary refill. Heart rate and blood pressure are measured, usually by placing the patient on a telemetry monitor. The presence of gross jugular venous distention should be sought, as it indicates heart failure/volume overload or circulatory obstruction.

Resuscitative vascular access is an early, crucial priority. In the non-exsanguinating

critically ill patient, prompt placement of a short, large-gauge catheter into a peripheral vein is usually sufficient for initiating the first phase of treatment. The patient with life-threatening hemorrhage requires an additional high-flow cannula—either a 16-gauge or larger angiocath or a 7-Fr or larger introducer placed in a large peripheral or central vein—to facilitate transfusion at the outset of care. If intravenous access is unable to be obtained immediately, an intraosseous catheter should be inserted without delay.

The most important therapies to support circulation to consider in the primary survey are crystalloid and blood. Epinephrine is indicated in the primary survey when anaphylaxis is a high concern.

An electrocardiogram (ECG) may be obtained in the primary survey when the patient is suspected to be critically ill from an arrhythmia or acute coronary syndrome. Unstable tachycardias are shocked and unstable bradycardias are paced at this juncture unless an immediately reversible cause is identified. Perhaps the most important of these is hyperkalemia, which is common and dangerous enough that calcium therapy should be specifically considered in the primary survey, especially in renal failure patients.

D: neurologic Disability

The initial evaluation of neurologic disability is four maneuvers: assessment of level of consciousness and mentation; pupillary size, symmetry, and reactivity; movement at four extremities; and capillary glucose measurement.

Level of consciousness is adequately described in the primary survey as either agitated, alert, responsive to verbal stimuli, responsive to painful stimuli, or unresponsive to painful stimuli. Agitation or confusion can be as ominous as obtundation as a marker of serious disease.

All patients with neurologic signs should have hypoglycemia either excluded or empirically treated. Signs of brain herniation may be treated straightaway with mannitol or hypertonic saline. Early brain imaging is appropriate

in patients thought to be critically ill from a structural brain lesion.

E: Exposure

Patients who require resuscitation should have all clothing removed and every inch of skin examined as early as can be done safely. Evidence of trauma, rashes, medication patches, medical alert tags, scars, and medical devices often direct care and are easily missed unless sought. If the history is incomplete, clothing and possessions should be inspected for clues.

A rectal temperature can be taken at this time, and active warming or cooling is initiated in the primary survey when indicated.

F: Family and friends

Many patients who require resuscitation cannot provide a complete history, making the collateral history offered by EMS, family, companions, or other providers crucial. Goals of care should be clarified or established early, when appropriate. In cardiac arrest, offer family the opportunity to be present during the resuscitation. Otherwise, provide an early report to the family, erring on the side of cautious prognosis. Language like I'm very concerned usually appropriately sets expectations and conveys a suitable degree of uncertainty.

G: analgesia

Pain should be rapidly, aggressively treated as a primary goal of care but also to reduce catecholamine release. Intravenous opiates are first line in most cases: Fentanyl offers rapid onset of action and is an excellent initial choice, followed by longer-acting agents such as morphine or hydromorphone. Analgesic-dose ketamine (0.15 mg/kg) is an effective alternative or addition when opiates are ineffective or not desired.³ Intramuscular or subcutaneous dosing should be provided to the patient in severe pain if intravascular access is not immediately available.

H: Human chorionic gonadotropin

Pregnancy may be occult and usually changes the trajectory of resuscitation; it must be specifically considered early in the care of any ill woman of childbearing age. This is most easily accomplished by placing two drops of blood on

a standard urine human chorionic gonadotropin (hCG) cassette assay.⁴

The uterus of the hypotensive late trimester patient should be manually displaced to the left. A woman who presents arrested or nearly arrested with a gravid abdomen should be considered for perimortem caesarean section.

I: Infection

Isolation of patients who may have dangerous communicable illness is an essential step when indicated. Patients thought to be critically ill from an infection should have appropriate cultures drawn and promptly treated with broad-spectrum antibiotics. Early source control, such as the removal of an infected catheter or surgical debridement of infected tissue, may be lifesaving and should be initiated as rapidly as practicable.

J: ultrasound Jel

Point-of-care sonography is indicated early in the management of all patients with hypotension of uncertain etiology to narrow the differential diagnosis, guide procedures such as vascular access, and direct fluid resuscitation. Specific ultrasound techniques will be highlighted in the following sections.

Emergency Airway Management

The Decision to Intubate

Endotracheal intubation (ETI) is the most dangerous procedure that most resuscitators routinely perform. While performing ETI on a patient who would have done well without it is suboptimal, delaying or omitting ETI when it is required is much more likely to result in patient harm. Understanding the indications for intubation is therefore a cardinal skill for providers who care for the critically ill; these are summarized in [Table 2–2](#).

Anatomic airway lesions—especially dynamic airway lesions mentioned earlier—can progress rapidly and demand a particularly aggressive, early airway strategy that also accounts for their expected difficulty. Disorders of breathing are the most common reason for ETI in most environments but are also the most treatable with noninvasive ventilation, as discussed later. Failure to protect the airway from neurologic disability is classically confirmed by the

TABLE 2–2 Indications for intubation.

Anatomic airway compromise: neck trauma, angioedema/anaphylaxis, thermal or caustic exposures, mouth and neck infections, tumor, oral bleeding.
Failure of oxygenation or ventilation (breathing): asthma/COPD, pulmonary edema, pneumonia.
Support tissue oxygen delivery (circulation) by unloading the muscles of respiration: sepsis, multiple organ dysfunction syndrome.
Neurologic failure to protect the airway (disability): intracranial catastrophes (stroke, trauma), profound central nervous system (CNS) depression, status epilepticus. Neuromuscular weakness syndromes (myasthenia gravis, amyotrophic lateral sclerosis (ALS), Guillain-Barré syndrome) may cause critical airway or breathing embarrassment depending on whether they primarily insult airway reflexes or the muscles of respiration.
Expected clinical deterioration, especially if the patient is to be moved away from a resuscitation bay (to radiology or another institution).
A fighting patient—especially with high concern for an associated dangerous condition—too agitated to properly manage without aggressive sedation.

absence of a gag reflex, but this is no longer considered good practice because a significant portion of the population has a poor gag reflex, and performing an emetogenic stimulus on a patient with compromised airway defenses is dangerous.⁵

Preparation for Endotracheal Intubation

In optimal airway management technique, preparation is deliberate and meticulous, while the procedure itself is brief and anticlimactic. Preparation is divided into preoxygenation, cognitive readiness, and material readiness. In addition to complex decision making, ETI requires many simple steps that, when accidentally omitted, can bring disaster; we therefore strongly recommend using a checklist ([Figure 2–1](#)).

Preoxygenation should start as soon as the decision to intubate is made. In addition to large-volume oxygenation techniques, all patients should be oxygenated with a nasal cannula, which augments conventional maneuvers and provides positive pressure oxygenation during the airway attempt, prolonging safe apnea time.⁶ Most patients can be fully preoxygenated with a reservoir face mask. Patients who do

not saturate better than 95% with a non-rebreathing face mask likely have a physiologic shunt and will quickly desaturate during the airway attempt; pre-oxygenation is in these cases therefore ideally done with noninvasive ventilation.⁷ Patients whose respiratory effort is insufficient to oxygenate with high-flow supplemental oxygen should have respirations assisted by bagging across a face mask or via a supraglottic airway device.

Patients who are too agitated to allow adequate oxygenation are more safely managed by using dissociative sedation to facilitate oxygenation. Delayed sequence intubation calls for the administration of induction-dose ketamine (1 mg/kg IV over 30 seconds with additional doses of 0.5 mg/kg as needed), followed by closely monitored application of usual preoxygenation technique, followed by the administration of a paralytic and commencement of the airway attempt.⁸

Cognitive readiness entails assessment of the patient’s physiology and difficult airway features to develop an airway strategy that includes a specific plan for failure of intubation and failure of ventilation; the roles of all team members should be clearly defined at this stage. Material readiness stipulates that all equipment that may be needed for initial and failed airway management is either at bedside or is located and quickly available.

Airway Strategy

Most patients are best intubated using rapid sequence intubation (RSI), the simultaneous administration of an induction agent and paralytic, followed by laryngoscopy. T rough paralysis, RSI immediately provides optimal intubating conditions and reduces the likelihood of aspiration. RSI also renders the patient apneic, however, and ventilation must be established before critical desaturation occurs. RSI therefore may not be the best choice when laryngoscopy is predicted to be difficult or when maneuvers to rescue failed laryngoscopy—bag mask ventilation and cricothyrotomy—are expected to be difficult (Table 2–3).

T e most important alternative to RSI is awake intubation, which uses local anesthesia and systemic sedation to facilitate laryngoscopy while spontaneous respirations are preserved. T e more difficult the airway features and the less procedural urgency, the more likely awake intubation should be used instead of RSI.

Laryngoscopy

Direct and video-assisted laryngoscopy are the chief airway management techniques in most resuscitation environments. Video laryngoscope devices that utilize a standard geometry (eg, Macintosh) blade offer the advantages of video laryngoscopy (better view of the glottis, viewable by others who can thus advise or assist) as well as the advantages of direct laryngoscopy (easier tube delivery, no soiling of camera). For either direct or video laryngoscopy, the patient should be optimally positioned with the external auditory meatus parallel to the suprasternal notch; in obese patients this often means building a “ramp” of sheets under

upper back, shoulders, neck, and head. Inclining the torso 15° to 45°, either by raising the head of the bed or using reverse Trendelenburg position, improves glottic view and oxygenation as well as reducing the likelihood of regurgitation or emesis, and should be used routinely but especially in obese or vomiting/hematemesis patients.^{9,10}

The laryngoscope of either a direct or video device should be inserted into the mouth under direct vision. Once the blade has controlled the tongue, gaze may be shifted to the video monitor. The first goal is to visualize the epiglottis; once identified, the blade is positioned to lift the epiglottis and expose the vocal cords. If an adequate view of the glottis is obtained, the endotracheal tube may be delivered at this point—if using video, advance the tube under direct vision until the tip of the tube approaches the end of the blade, then return gaze to the screen. Inadequate views may be enhanced by an assistant performing jaw thrust, repositioning of the head, or external manipulation of the larynx.¹¹ Poor glottic views may be intubated using a gum elastic bougie; we recommend using the bougie routinely so that its advantages may be skillfully leveraged in difficult airway scenarios.

As soon as these maneuvers have failed to produce an intubatable view of the glottis, or significant desaturation has occurred, laryngoscopy should be aborted and ventilation established. Bag mask ventilation is more likely to be effective and less likely to dangerously insufflate the stomach if nasal and oral airways are placed and the mask is applied to the face with two hands, the Ambu bag compressed by an assistant. Alternatively, when laryngoscopy has failed, immediate ventilation through a supraglottic airway device is both easier and more effective than bag mask ventilation.

Once ventilation is established and the patient is reoxygenated, the equipment, modality, patient position, or operator is changed and another airway attempt is undertaken. If after failed intubation ventilation and oxygenation also fail, it is imperative that a surgical airway be initiated early, before critical desaturation.

Postintubation Management

After tracheal position is confirmed by capnography, supracarinal position is confirmed by auscultation of

both lungs. The tube is secured and postintubation analgesia and sedation are initiated. In the just-intubated patient, it is appropriate to provide aggressive sedation, as the patient may still be paralyzed and require invasive procedures or transport. Once the patient has settled and is stable on the ventilator, sedation should be lightened to a more physiologic level of arousal.

Noninvasive Ventilation

Noninvasive ventilation (NIV, variously referred to as noninvasive positive pressure ventilation [NIPPV], CPAP or BiPAP]) uses a ventilator attached to a tight-fitting mask that covers the nose or both the mouth and nose to deliver oxygen at positive pressure. NIV has emerged as a valuable therapy in the management of various types of respiratory failure. In particular, the care of patients with pulmonary edema, decompensated chronic obstructive pulmonary disease (COPD), and severe asthma has been transformed by the application of NIV in resuscitation environments. To realize the potential of NIV to reduce the incidence of ETI and its attendant morbidity, all equipment and expertise needed to initiate NIV must be present at the point of care, that is, clinicians are able (and encouraged) to initiate NIV without summoning assistance or materials from outside the department.

Arrested patients require invasive ventilation techniques, and full face mask NIV should not be used if vomiting is a high concern, however most other patients with respiratory failure of any type deserve a trial of NIV, if only as preoxygenation while preparations are being made for ETI. NIV is appropriate for use in patients with noncurative goals of care,¹² and has an emerging role in supporting ventilation during procedures that require deep sedation or analgesia.¹³

Hypotension

Along with airway and breathing embarrassment, the management of patients with circulatory compromise, as evidenced by hypotension and/or hypoperfusion, is a foundational charge of the resuscitator. Empiric therapies to support circulation are instituted in the primary survey as the differential diagnosis—perhaps the most important in resuscitation medicine—is considered (Table 2–4).

TABLE 2–4 Hypotension differential diagnosis.

Metabolic Hypoadrenalism Hypo/hyperthyroidism Hypocalcemia
Spurious Equipment or technique failure

Bedside Sonography for Hypotension

Goal-directed point-of-care ultrasound has assumed a central role in the management of patients with undifferentiated hypoperfusion states. Bedside

sonography can be quickly performed in the resuscitation bay simultaneously with other maneuvers, is noninvasive, repeatable, and powerfully enhances the diagnostic power of the history and physical examination.¹⁴

The evaluation of traumatic hypotension was among the earliest indications for nonradiologist-performed ultrasound.¹⁵ Focused Assessment with Sonography for Trauma (FAST) entails a series of targeted ultrasound windows (Table 2–5) to rule in common causes of hypotension in blunt or penetrating trauma. FAST has reduced computed tomography (CT) use, marginalized invasive diagnostic peritoneal lavage (DPL), and improved patient-oriented outcomes in the management of trauma.¹⁶

Bedside sonography is of high utility in both the diagnosis and management of atraumatic hypotension. The Rapid Ultrasound for Shock and Hypotension (RUSH) examination outlines a goal-directed algorithm¹⁷ which has been supplemented with additional assessments since its inception to produce a comprehensive evaluation of the hypoperfused patient.¹⁸

Focused echocardiography is often of great value in hypotension. The parasternal long-axis view is generally used to identify pericardial effusion and, if present, to assess for diastolic collapse of the right atrium and ventricle, suggesting tamponade physiology. The apical four-chamber view can be used to assess for right ventricular dilation and paradoxical motion of the interventricular septum; this is evidence of pulmonary hypertension, raising the specter of pulmonary embolism as the etiology of hypotension.¹⁹ Left ventricular contractility, qualitatively assessed in parasternal long or short axis,

TABLE 2–5 Focused assessment with sonography for trauma.

Subxiphoid view of the heart: Is there a pericardial effusion?
Hepatorenal space: Is there fluid in the right upper quadrant?
Splenorenal space: Is there fluid in the left upper quadrant?
Rectovesical space: Is there fluid in pouch of Douglas?
Lung apices: Is there a pneumothorax?

is classified as hyperdynamic (as seen in hypovolemia), normal, or depressed (seen in coronary ischemia, cardiomyopathy, or myocardial depression from sepsis). Left ventricle (LV) function may also be used to guide the administration of IV fluids and vasoactive drugs.

Respirophasic variation in diameter of the inferior vena cava (IVC), as measured by bedside sonography, has been shown to correlate with central venous pressure and intravascular volume, and may predict fluid responsiveness.²⁰ The IVC is readily assessed in its longitudinal axis and measured 2 cm from its entrance into the right atrium; the greater the variation in the diameter of the IVC with respiration, the more likely the patient is to benefit from fluid administration.

Lung ultrasound is used to exclude pneumothorax, as in trauma, by visualizing sliding of the visceral pleura on the parietal pleura with the linear array probe positioned at the third intercostal space, midclavicular line. Pulmonary edema

is identified sonographically by the prevalence of hyperechoic vertical beam artifacts, B-lines, that arise at the interface of water and air. The presence of three or more B-lines per field indicates interstitial fluid and, together with LV and IVC assessment, can be used to predict fluid responsiveness (Figure 2–2).²¹

In appropriate circumstances, the abdomen is assessed for free fluid, as in the FAST examination, which in medical resuscitation could indicate bleeding or ascites. The aorta is imaged for aneurysm from its origin inferior to the xiphoid process to its iliac artery bifurcation point; diameter greater than 3 cm is abnormal with higher likelihood of rupture greater than 5 cm.

If pulmonary embolism is in the differential, bedside two-point compression sonography of the femoral and saphenous veins accurately detects deep vein thrombosis (DVT).²²

Lastly, ultrasound is used to guide resuscitative venous access, pericardiocentesis, paracentesis,

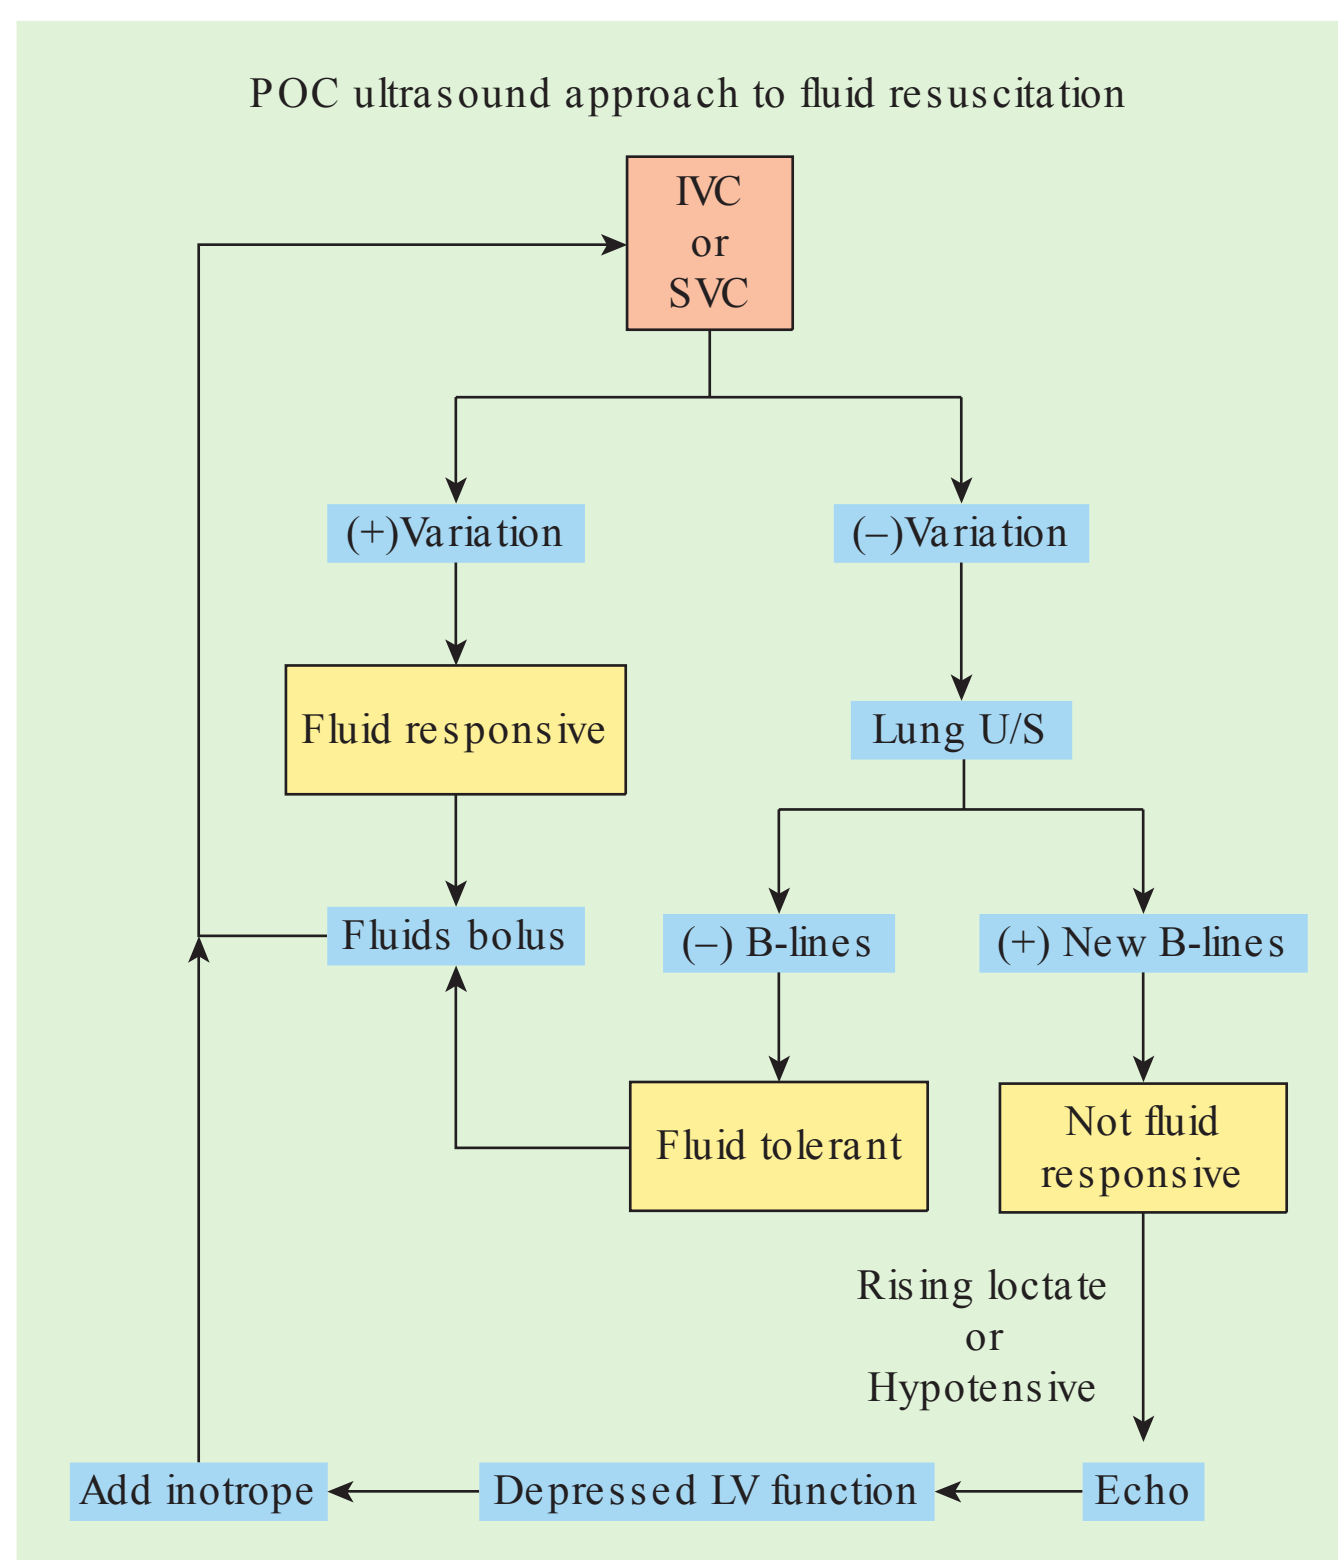

FIGURE 2–2 Point-of-care (POC) ultrasound approach to fluid resuscitation.

chest drainage, and lumbar puncture, as well as determine endotracheal tube position.²³

Resuscitation Goals and Therapies in Hypotension

Blood pressure is the most basic proxy for tissue perfusion, and remains a valuable guide to therapy, with a mean arterial pressure (MAP) of 65 mm Hg often used as a target.²⁴ A more reliable indicator of successful resuscitation, however, is end-organ function. Normal mentation, urine output, and skin quality demonstrate adequate perfusion, though young, healthy patients have high physiologic reserve and may not manifest hypotension and organ failure despite significant perfusion deficit.

Serum lactic acid clearance has emerged as a powerful resuscitation barometer and predictor of patient outcome in a variety of shock states^{25,26} and is recommended as a resuscitation goal by the Surviving Sepsis Campaign.²⁷ While treatment-resistant hyperlactatemia is an ominous sign demanding a diagnostic and therapeutic reevaluation, a significant proportion of decompensated, critically ill patients will have normal lactate levels.²⁸ Serum lactic acid—like all resuscitation parameters—should therefore be interpreted as a single data point in a larger clinical context.

Patients shocked by traumatic hemorrhage may benefit from lower blood pressure targets until bleeding is controlled.²⁹ Critically injured patients may benefit from titrating therapy to a sympatholytic blood pressure target, using fentanyl to attenuate catecholaminergic vasoconstriction.³⁰

The cardinal therapy for hypotension and shock is identification and treatment of its underlying cause. Empiric management often begins with intravenous fluids, with colloidal preparations such as albumin demonstrating no benefit over crystalloid in most studies.³¹ Normal saline or lactated Ringer solution are appropriate choices for initial fluid resuscitation; patients with high fluid requirements should be transitioned to more balanced solutions or fluid preparations tailored to their physiology.³² The utility of additional fluid and the relative balance of fluids and vasopressors in the individual hypotensive patient remains a central resuscitation challenge. The ideal test of fluid responsiveness demonstrates an augmentation of cardiac output

TABLE 2–6 Tests of fluid responsiveness.

Central venous pressure (CVP)

Pulse pressure variation
Inferior vena cava diameter variation
Superior vena cava diameter variation
Passive leg raise

with fluid challenge. When direct measurement of cardiac output is not feasible, a variety of surrogates have been used to predict and evaluate the benefit of volume (Table 2–6). Vasopressors are traditionally added when the patient is thought to be volume replete or fluid unresponsive; however, especially in distributive shock, earlier use of low-dose pressor infusions may be of benefit.³³ Although data are not definitive,³⁴ norepinephrine is often recommended as the first-line vasopressor in many shock states.²⁷

Blood products should be used sparingly in medical resuscitation. Current recommendations call for empiric packed red blood cell transfusion when hemoglobin levels fall below 7 g/dL,³⁵ though higher targets may be considered in coronary ischemia or if perfusion goals are not met despite optimization of other resuscitation parameters.³⁶ Conversely, hypoperfused trauma or hemorrhaging patients should receive little if any crystalloid in favor of warmed blood products, ideally as part of a transfusion protocol that balances red cells with platelets, plasma, cryoprecipitate, and calcium.³⁰ Most transfused trauma patients should also receive the procoagulant tranexamic acid,³⁷ and in critically bleeding patients underlying coagulopathy should be deliberately sought and treated with appropriate agents such prothrombin complex concentrate, desmopressin (ddAVP), and vitamin K.

Cardiac Arrest

The management of atraumatic cardiac arrest starts with the immediate provision of supportive

therapies, followed by consideration of specific therapies to address the precipitating cause. After cardiac arrest has been identified, if resuscitation is consistent with the goals of care, the earliest priority is the initiation of chest compressions at a rate of at least 100 per minute, a depth of approximately 2 in, and allowing full recoil between compressions. If a chest compression device is not used, the compressor should be switched at regular, brief intervals to maintain quality. Chest compressions should proceed with minimal interruption until return of spontaneous circulation, implementation of extracorporeal life support, or pronouncement.

The determination of the cardiac rhythm and defibrillation of pulseless ventricular tachycardia or ventricular fibrillation should occur as early as feasible and at regular intervals thereafter. Vascular access is established with large-bore peripheral venous catheters or an intraosseous catheter. Ventilation may be initiated using a supraglottic device such as an laryngeal mask airway (LMA), to be replaced with an endotracheal tube if needed for gas exchange or definitive airway control. Most arrested patients should be ventilated with an explicitly low rate and volume, preferably using a mechanical ventilator. The empiric use of vasopressors and anti-dysrhythmics in cardiac arrest is recommended by widely adopted guidelines³⁸ and is routine in most environments. The use of specific intra-arrest therapies is guided by history, physical examination, and ultrasound (Table 2–7).

Continuous capnography should be initiated at the outset of cardiac arrest care to verify the efficacy of ventilation (through bag mask, supraglottic device, or endotracheal tube) and monitor intra-arrest care. End-tidal CO₂ (ETCO₂) reflects cardiac output and a drop in ETCO₂ often indicates chest compressor fatigue.³⁹ Return of spontaneous circulation is detected by a sudden rise in ETCO₂ and an ETCO₂ value persistently less than 10 mm Hg predicts failure of resuscitation.⁴⁰ When supportive therapies have been provided and reversible causes of cardiac arrest are considered and addressed, ongoing cardiac arrest predicts a poor likelihood of successful reanimation (in the absence of extracorporeal oxygenation).⁴¹ A low ETCO₂ value and the absence of sonographic cardiac contractility are often used as further evidence of poor recoverability

Intracranial catastrophe (CVA, SAH)

CVA, cardiovascular accident; SAH, subarachnoid hemorrhage.

and an appropriate point to terminate efforts and pronounce the patient as deceased.⁴²

Emerging therapies in intra-arrest care include extracorporeal oxygenation and transesophageal echocardiography (TEE). In capable centers, selected patients in cardiac arrest are stabilized with emergency department–based ECMO, which replaces cardiac and pulmonary function while the underlying lesion is addressed. Extracorporeal cardiopulmonary resuscitation requires specialized equipment, training, and a multidisciplinary protocol, but can produce remarkable rates of neurologically intact cardiac arrest survival.^{43,44} Intra-arrest TEE provides anatomic windows to the heart and surrounding anatomy in detail not degraded by body habitus or lung disease, while allowing access to the chest for compressions and other procedures. TEE is more likely to identify the precipitant of arrest than TTE, provides real-time feedback on the adequacy of chest compressions, reveals electrocardiographically occult ventricular fibrillation,

and distinguishes pulseless electrical activity from pseudo–pulseless electrical activity (PEA) (myocardial contractions too weak to generate a pulse).⁴⁵

When return of spontaneous circulation (ROSC) is achieved, patients who do not have return of mentation should be maintained at 36°C.⁴⁶ Further efforts to determine the arrest precipitant should be undertaken if uncertain and the patient considered for immediate coronary angiography.⁴⁷ Priorities in postarrest care include lung-protective ventilation with normoxia, inotropic and vasopressor agents to address hypocontractility and hypotension, careful attention to glucose and electrolytes, and optimization of end-organ perfusion.

External chest compressions and vasoactive medications do not benefit patients who arrest following trauma.^{48,49} The management of traumatic arrest centers on prognostication based on mechanism, signs of life, and duration of cardiac arrest.⁵⁰ Appropriate patients should receive bilateral chest decompression and consideration for resuscitative thoracotomy, where pericardial tamponade is relieved and penetrating injuries to the heart or pulmonary vessels temporarily controlled, the aorta cross-clamped, and internal cardiac massage performed.⁵¹

Targeted Temperature Management After Cardiac Arrest

Oren A. Friedman, MD

KEY POINTS

- 1 Targeted temperature management (TTM) refers to the global practice of controlling temperature after cardiac arrest. Mild therapeutic hypothermia refers to a temperature between 32°C and 34°C.
- 2 The positive effects of TTM postarrest are believed to be related to its effects in suppressing the whole body reperfusion injury, and preventing exacerbation of that injury by hyperthermia.
- 3 Device therapy for TTM can be divided into surface cooling and invasive technology.
- 4 The three phases of TTM are induction, maintenance, and rewarming.
- 5 There is no consensus on the optimal rate of rewarming although it is recognized that uncontrolled or rapid rewarming can lead to vasodilation, hemodynamic instability, and dangerous electrolyte shifts.
- 6 The lack of pupillary reflexes 3 days postcardiac arrest, the presence of myoclonic status epilepticus (MSE), and the absence of somatosensory-evoked potentials (SSEPs) all very likely portend an extremely poor prognosis.

The implementation of therapeutic hypothermia (TH) and targeted temperature management postcardiac arrest has arguably been one of the most significant contributions to resuscitation care. It should be viewed as the most important intervention in the postresuscitation period.

HISTORY OF HYPOTHERMIA

The modern application of TH had its origins in the 1950s. In 1956, Bigelow pioneered the use of hypothermia for neurologic protection during cardiac surgeries, a practice that has since become standard.¹ In 1964 Peter Safar's historic paper "the first ABC's of resuscitation" recommended the use

of hypothermia after cardiac arrest in patients who do not regain consciousness after return of spontaneous circulation.² Physicians hypothesized that hypothermia's ability to suppress metabolic activity would translate into a tissue preservative capacity. Low target temperatures were used to accentuate the reduction in metabolism. However, a core body temperature below 30°C which we now refer to as "deep hypothermia," exposes patients to the dangers of cardiac instability. Presumably whatever beneficial effects existed at these temperatures were outweighed by harm, and the therapy was abandoned. Then the 1980s and 1990s saw the emergence of animal research on the beneficial effects of "mild hypothermia." Mild TH, that is a temperature between

32°C and 34°C, has profound effects on stemming reperfusion injury, without the deleterious consequences of cardiac instability.

INTRODUCTION INTO MODERN PRACTICE

The modern framework of TH postcardiac arrest stems from two landmark trials in the New England Journal of Medicine in 2002. The larger study known as the “Hypothermia after Cardiac Arrest (HACA) trial” was a multicenter randomized controlled trial (RCT) in Europe involving 273 postventricular fibrillation (VF)/ventricular tachycardia (VT) cardiac arrest patients who were randomized to either cooling to 32°C to 34°C for 24 hours, or “normothermia.” The normothermia control group did not have any temperature management. The neurologic outcome at 6 months was favorable in 55% of the hypothermia patients versus 39% of the control group.³ The second major trial enrolled 77 patients in Australia with out-of-hospital arrest from VF. At hospital discharge 49% of patients who were cooled went home or to rehabilitation, versus only 26% in the control group.⁴ The odds ratio for a favorable neurologic outcome with TH was 5.25 (95% confidence interval [CI], 1.47-18.76; P = 0.01), after adjustment for age and duration of the arrest.

It is important to note that two studies investigated patients with out-of-hospital electrical arrests who remained unconscious. The International Liaison Committee on Resuscitation (ILCOR) published a recommendation to use TH after electrical arrests in 2003. The most recent recommendations from the

American Heart Association (AHA) in 2010 gave hypothermia after VF/VT a class I recommendation and a class IIb for pulseless electrical activity (PEA)/asystole.⁵

Since the two initial RCTs targeted a temperature range between 32°C and 34°C, the majority of centers began targeting a temperature of 33°C. In late 2013, the large multicenter trial known as the Targeted Temperature Management (TTM) trial randomized 950 postarrest patients to a temperature target of 33°C versus 36°C for 28 hours, and demonstrated equivalent mortality and neurologic outcome.⁶ It is emphasized that temperature was tightly controlled in both arms, as opposed to the earlier two trials in which the control group was allowed to become hyperthermic. The study included all rhythms, but a prespecified subgroup analysis of VF/VT also failed to show a difference between the two temperatures. Given how recent this important article was published, it remains to be seen how this will impact provision of TH. Most of the knowledge surrounding the practice of temperature management after cardiac arrest derives from studies and experience targeting a temperature of 33°C. One option many will take is to change to a target of 36°C in all patients. There could also be more variability in targeted temperatures going forward. While it is reasonable to continue to cool to 33°C in many patients with VF or VT as the presenting rhythm, for those with higher cooling risk (ie, more hemodynamically unstable, more bleeding concerns) and/or less clear clinical benefit (PEA, asystole), a temperature target of 36°C may be a better alternative (Table 3–1).

TABLE 3–1 Landmark trials of therapeutic hypothermia.

Trial	Study Group	Intervention	Outcome
HACA 2002 (n = 253)	Out of hospital VF/VT	32°C-34°C for 24 h vs normothermia ^a	Improved neurologic outcome and mortality at 6 mo
Bernard 2002 (n = 77)	Out of hospital VF	32°C-34°C for 12 h vs normothermia ^a	Improved good outcome at discharge ^b
TTM2013 (n = 950)	Out of hospital all rhythms	33°C versus 36°C for 28 h	Equivalent neurologic outcome and mortality at 6 mo

^aNormothermia groups were allowed to be hyperthermic.
^bGood outcome was defined as discharge to home or rehabilitation center.

To clarify terminology, TTM will refer to the global practice of controlling temperature after cardiac arrest and the “TTM trial” will refer to this above study. TH will refer to a target temperature of 33°C, and minimal hypothermia (MH) will refer to a target temperature of 36°C.

WHY HYPOTHERMIA IS BENEFICIAL

The therapeutic value of TH is believed to lie mainly in its ability to decrease reperfusion injury. Cells subject to ischemia become injured and stunned, but do not necessarily undergo cell death immediately. A large proportion of the cytotoxicity from broad ischemic injury occurs in the period of time following tissue reperfusion. Ischemic cells have lost normal oxidative and metabolic function and an immediate burst of oxygenated free radicals and mitochondrial damage occurs on reperfusion. A second phase of injury involves inflammation, apoptosis and necrosis, which can play out over hours to days. Numerous complicated pathways of reperfusion injury include but are not limited to intracellular calcium and glutamate dysregulation, proinflammatory cytokines, and complement activation.¹ Hypothermia impacts this cascade at multiple steps, stemming calcium and glutamate imbalance, reducing oxidative damage, and ultimately decreasing apoptosis.⁷ The brain is particularly susceptible to ischemia-reperfusion injury, and particularly sensitive to temperature. However, in cardiac arrest, the ischemia is global, and damage is widespread. There is reason to believe that systemic cooling as opposed to local brain cooling accounts for some of the impact of TH in reducing mortality. It is not clear how low of a temperature is required to have clinical benefit, and the TTM trial suggests minimal hypothermia may be enough. Hyperthermia (fever) exacerbates the reperfusion injury, and may explain why its prevention alone has therapeutic potential. The TTM trial also raises the question of whether simply preventing hyperthermia has enough therapeutic power as to negate any beneficial effects of lower temperature.

In summary the positive effects of TTM postarrest are believed to be related to its effects

in suppressing the whole body reperfusion injury, and preventing exacerbation of that injury by hyperthermia.

WHO TO COOL

Neurologic Status After Arrest

TTM is not recommended for patients who have clear return to baseline neurologic status after their arrest. Criteria for enrollment in the HACA trial was the inability to follow verbal commands; the Australian study used the more vague description of “unconscious,” and the recent TTM trial specified a Glasgow Coma Scale (GCS) less than 8. It is not known whether there is any benefit to TTM in patients who have less severe neurological examinations postreturn of spontaneous circulation (ROSC). The 2010 AHA guidelines recommend TH for patients who have a lack of meaningful response to verbal commands,⁵ and it is reasonable to apply this criteria to TTM in general. As for patients who may have received sedatives thereby confounding their presenting examination, it may be prudent to wait a reasonable period to see if they regain the ability to follow commands before deciding to cool. It is suggested not to provide TTM in patients who are severely neurologically impaired at baseline, terminally ill, those for whom intensive care does not seem appropriate, or in whom they or their surrogates have indicated that they would not want intensive care.⁷

Location and Other Rhythms

In terms of location, the core studies were limited to out-of-hospital arrests. Accumulating evidence however supports TH for in-hospital arrests, and aside from the higher proportion of nonarrhythmic arrests there is no reason to believe the difference in physical location would have any detrimental impact on the therapy. Although TH is best established in VF and VT arrests, there has always been interest in its application to nonshockable rhythms. Irrespective of the dominant rhythm during cardiac arrest, ischemia and reperfusion injury occurs and may therefore be responsive to TH. The 2015 AHA guidelines gave a class I recommendation that all

comatose patients post ROSC irrespective of rhythm receive TTM in the range between 32°C and 36°C.⁶ A large retrospective study in 2011 showed that TH was associated with improved outcomes in out-of-hospital nonshockable rhythms.⁸ However, a recent prospective review of a French registry from 2000 to 2009, did not find improved outcomes of TH in PEA/asystole patients.⁹ The authors raised the possibility that the anoxic/hypoxic insult in nonarrhythmic arrests is likely much greater and therefore may require deeper or longer periods of hypothermia to address. On the other hand, it is also possible that the risk-benefit ratio may simply be altered in this high-risk population and that PEA and asystole are better served by targeting a (potentially safer) temperature of 36°C. In conclusion, data supporting TH (33°C) in PEA/asystole are lacking and the benefit of TTM in general in this population is not clear. However, given the physiologic rationale for benefit of TH, it is arguable to target a potentially safer goal of 36°C.

Physiologic Effects of Cooling

The following sections on the physiologic effects of cooling refer mainly to a temperature of 33°C. The effects of minimal hypothermia (36°C) are less well characterized, but presumably milder.

Cardiovascular Effects

Hypothermia raises systemic vascular resistance (SVR) but its effects on blood pressure are variable as are its effects on cardiac output. The hypothermic heart develops diastolic dysfunction and there is an expected and physiologically adaptive bradycardia. It is not uncommon to see heart rates (HRs) in the low 40s (occasionally high 30s) with core temperatures of 33°C. Artificially elevating the HR could result in worsening contractility and cardiac output.¹⁰ Therefore, it is not recommended to treat bradycardia (with catecholamine infusions or pacing) unless evidence suggests it is directly responsible for poor perfusion. Mild TH has an antiarrhythmic effect and suppresses the development of ventricular arrhythmias. But overcooling should be avoided because a core temperature under 30°C frequently results in cardiac arrhythmias including spontaneous VF.¹¹

Although initial studies excluded hemodynamically unstable patients, increasing experience shows the safety in TH even in very unstable patients. A case series of patients in cardiogenic shock post-cardiac arrest from acute coronary syndrome (ACS) on multiple vasopressors/inotropes including a large percentage requiring intra-aortic balloon pumps reported the safety of TH.¹² Another study of cardiac arrest patients from ACS suggests that TH may have a favorable impact on the hemodynamics of cardiogenic shock. Hypothermic patients had a higher SVR and HR. But more surprisingly, they also had improved cardiac output and index¹³ (as measured by a minimally invasive cardiac output monitoring device and echocardiography).

Neurologic

The brain is particularly sensitive to ischemic injury and temperature. For every decrease in 1°C, brain metabolism decreases by 6% to 7%.¹ There is abundant evidence that hyperthermia is associated with poor outcomes after many different brain injured states (stroke, traumatic brain injury). Postcardiac arrest cerebral edema may be more common than readily recognized and hypothermia is very effective in lowering intracranial pressure (ICP). Lastly, TH may provide an anti-antiepileptic effect.¹⁴

Hematologic

It has been long recognized that hypothermia potentiates coagulopathy during trauma and surgery. Accidental hypothermia is widely considered a marker of mortality in trauma victims, as well as a marker of morbidity during surgery. The oft-repeated bloody vicious triad of trauma “hypothermia, coagulopathy, and acidosis,” is thought critical to avoid. Studies of TH effects on coagulation demonstrate a prolongation of prothrombin time (PT) and activated partial thromboplastin time (aPTT), as well as reversible thrombocytopenia and platelet dysfunction.¹⁵ A mild prolongation of time to clot formation, but not clot propagation or clot firmness using more sophisticated clotting testing (ROTEM) has also been found.¹⁶ However, while unintentional hypothermia may be important to avoid during massive resuscitation of a bleeding patient, the clinical relevance of its effects on coagulopathy in controlled hypothermic

conditions however is less clear. Importantly, major clinical studies have not shown a significant increase in bleeding. There is accumulated experience of TH safely being applied concurrent with heparinization for pulmonary embolism, as well as in extremely anticoagulated patients with ACS (who may receive aspirin, clopidogrel, or heparin). Routine intensive care unit (ICU) procedures such as arterial and venous catheterization should not be affected by TH. In summary, the coagulopathy of TH is well tolerated, and safe with concurrent anticoagulation, but should be considered contraindicated in patients who arrest secondary to bleeding, especially those with ongoing uncontrolled bleeding. TH at 36°C is expected to have trivial effects on coagulation.

Renal/Electrolytes

A major concern is the effect of TH on potassium. Induction of hypothermia drives intracellular flux of potassium and the reverse occurs upon rewarming. Hypokalemia on induction is usually not a huge problem, but caution and possibly intervention should be taken in the hyperkalemic patient before rewarming. Magnesium levels mimic potassium, falling on cooling and rising again on rewarming. Hypophosphatemia is also common but rarely a problem. Hypothermia also inhibits insulin sensitivity and release leading to hyperglycemia.¹⁵ TH may lead to an increase in urine output, dubbed the “cold diuresis.” Whether this is related to a more centrally distributed circulation or a direct tubular effect is not clear.

Immune Suppression

TH is thought to be immunosuppressive but the degree is not well characterized, and may do not have clinical relevance. Pneumonia is common after cardiac arrest in general, and it is unclear if TH increases that risk. It is possible that TH can indirectly lead to an increase in infections by requiring sedation, paralysis, and mechanical ventilation.

Acid Base

As temperature falls the solubility of gases in the blood decreases. Temperature uncorrected arterial blood gases (ABGs) therefore overestimate both P_{CO_2} and P_{O_2} . The patient therefore may have a slight respiratory alkalosis and be slightly

more hypoxemic. The significance of this effect is unknown, and it is controversial whether to aim for a normal pH (pH stat) or normal CO_2 (alpha stat) level during TH. It is likely that the impact is more important at deeper levels of hypothermia used during cardiopulmonary bypass. This author recommends addressing the pH/ P_{CO_2} on the uncorrected ABG as you would any other critically ill patient, but aim for a slightly higher P_{O_2} than normal (ie, 70 mm Hg) to give buffer room.

In summary, TH routinely leads to well-tolerated bradycardia and electrolyte shifts. Other effects such as coagulopathy, immune suppression, and acid-base imbalances, are uncommon severe problems. TH effects on any of these conditions are expected to be minimal.

PRACTICAL CONSIDERATIONS OF TTM

1. Measuring temperature
2. Device therapy
3. Controlling shivering

Measuring Temperature

Surface or tympanic temperature measurements are not accurate enough for implementation of TTM. Core temperature monitoring via bladder or esophagus is recommended. Esophageal temperature rapidly reflects changes to core temperature, whereas bladder temperature may lag by 15 to 30 minutes as it equilibrates. Concern is raised in using bladder temperature probes with low or absent urine output, and therefore in a dialysis patient for example, esophageal monitoring is recommended.

Device Therapy

Good outcomes are possible with simple surface methods (ice packs, blankets); however the practice is very labor-intensive, messy, and less precise. Simple surface methods frequently lead to both over- and undershooting in temperature.¹⁷ Device therapy is recommended, as it provides strict control of temperature during the maintenance phase, while also allowing for a very steadily controlled rewarming rate. It is not clear that TH is easier (less deep temperature) to

achieve without device therapy, and therefore device therapy is still recommended.

Device therapy can easily be divided into surface cooling and invasive technology. Surface cooling devices typically circulate water through a cooling pad or blanket which relies on heat dissipation through the skin. Modern sophisticated devices work off feedback from a continuous core temperature monitor. Popular options include the Arctic Sun by Medivance and Medi-Term by Gaymar. There is also a cooling pad by EMCOOLS that is studied with multiple square-shaped conductors containing a proprietary water-graphite mixture called hydrocarbon.

Invasive devices require the insertion of a cooling catheter into a central vein (internal jugular femoral or subclavian). The device circulates cold fluid through the catheter cooling the blood by contact. Popular models include the CoolGuard and Termogard systems made by Zoll, and the InnerCool systems by Philips.

Studies directly comparing simple surface cooling methods to intravascular cooling showed equivalent outcomes but better temperature control with device therapy.^{18,19} But when compared against sophisticated surface devices there is no evidence that invasive cooling results in either faster cooling or decreased shivering. More important than the choice of device is being familiar with operating the device that you choose.

Extracorporeal cooling is very effective and convenient if the patient is already being placed on extracorporeal membrane oxygenation (ECMO) as part of their resuscitation, but this is not routine.

Controlling Shivering

If a patient is not achieving goal temperature target, the first consideration should be uncontrolled shivering. Shivering is not only counterproductive to cooling efforts but also detrimental to the critically ill patient who is unable to tolerate the high metabolic energy expenditure required to generate heat. This author has seen shivering lead to a drop in saturation of the central venous oxygenation ($S_{cv}O_2$) to the 50s only to see it normalize after the shivering was addressed with paralysis. Shivering can occur in very obvious gross myoclonic form, or may be so subtle as to not be visible to the eye. Sometimes

shivering can only be recognized by looking for baseline vibration artifact on the cardiac monitor tracing, or with electroencephalogram (EEG) monitoring (if present). Nonpharmacologic methods of shivering control such as skin counter warming have been explored, but virtually every patient undergoing TH will need pharmacologic control of shivering. Many medications have been successfully used to control shivering including opiates, benzodiazepines, propofol, and dexmedetomidine. Although there are subtle differences in response to one medication over another, there is no proof of a superior drug. Neuromuscular blockade (NMB) will definitively stop shivering and was used routinely in both of the 2002 trials and widely in the 2013 TTM trial. Although many have argued against using NMB during TTM, there is no proof of a deleterious effect, and this author believes that the downside of uncontrolled shivering far outweighs the potential of critical illness neuropathy. Many have reported an ability to stop paralytics or decrease sedatives once at 33°C, presumably due to suppression of the shivering reflex at a lower core temperature. Notably, in the TTM trial there was no difference in shivering between the 33°C and 36°C groups. It remains to be seen whether real-world practice will see less shivering at 36°C (because it is closer to normothermia) or more (because there will no longer be suppression of the shivering reflex). As always, the use of NMB should be accompanied by continuous sedation. For TH, this author favors starting continuous sedation and NMB on induction and continuing up through the rewarming phase.

THREE PHASES OF TTM (INDUCTION, MAINTENANCE, AND REWARMING)

Induction

Induction Techniques

Hypothermia devices can certainly be used for the induction phase of cooling. If cooling to 33°C, the only potential disadvantage of device therapy is a slow cooling rate (1°C-1.5°C per hour on average). A faster induction can be achieved with chilled IV saline. Kim et al showed that infusion of intravenous saline by emergency medical service (EMS) shortly

after ROSC was a safe and effective way to lower core body temperature by on average 1.5°C .²⁰ There was no evidence that cold saline led to recurrent arrests or significant pulmonary edema. Another small series of the use of intra-arrest cold saline showed that this could safely be done with the effect of lowering temperature by 2°C ,²¹ with a median time to reach 33°C of only 16 minutes. There is no evidence that mild TH inhibits ROSC and in fact one study showed that TH improves defibrillation success.²² Years of experience since the initial studies also supports the safety of IV chilled saline.

Chilled saline can either be kept ready in a refrigerator or can be made by placing a saline bag in ice water for 15 minutes. Induction can also be enhanced by placing ice packs over superficial vascular points including the neck, axilla, and groin.

Safety and Efficacy of Early Cooling

How early to start cooling, how fast to bring down the temperature, and how long to cool are areas of ongoing academic study. There is a multitude of animal data suggesting that earlier cooling is beneficial. One mouse study showed that intra-arrest cooling had better neurologic effects when compared with cooling initiated postarrest.²³ Certainly there is physiologic rationale to slow and prevent the reperfusion injury earlier on in the process, and like most interventions in resuscitation, the earlier the better.

In one recent trial, out-of-hospital arrest patients were randomized to prehospital cooling with IV saline versus cooling initiated in the emergency department (ED). There was no difference found in outcome, but due to the fast EMS response time and aggressive cooling in the ED, within 1 hour of arrival to the ED both groups were at the same temperature. The study, however, bolsters the safety of early IV cooling, and draws attention to the need for more trials addressing the topic.²⁴

The normal physiologic response to maintain thermostasis appears to be disturbed in sicker patients. Patients who are passively cooler post-ROSC, and who are less resistant to the induction of cooling tend to do worse overall. This phenomenon has complicated efforts to study time to goal temperature and outcome. Studies that have emerged seemingly linking earlier cooling to worse outcomes may reflect a selection bias toward sicker patients.²⁵

Most patients will have a significant drop in body temperature upon ROSC presumably due to heat loss, low metabolism, and low-flow state during the arrest. Rather than allowing the body to rewarm, the clinician can take advantage of the lower temperature and build upon it by either rapidly inducing TH, or maintaining the temperature at 36°C . The Fire Department of New York began intra-arrest cold saline administration in 2010.

How Late After Cardiac Arrest is too Late to Start Treating?

In the HACA trial it is important to note that target temperature was not reached for an average of 6 to 8 hours postarrest, a very long induction time compared to modern practice. There is animal research suggesting loss of benefit of hypothermia when started beyond 4 to 6 hours of ROSC.²⁵ However reperfusion injury postarrest occurs over hours to days, so if there is a delay in therapy for whatever reason, an impact may still be possible. Although it is reasonable to consider not treating if the patient is 8 hours post-ROSC, it is also important to emphasize that the upper limit of delay to implementation is not known.

Maintenance

Once at goal temperature, patients tend to stabilize. Temperature is continually monitored and controlled. Similarly, shivering is monitored and addressed. Aggressive critical care including ventilator management, replacing nonsterile lines, fluid resuscitation, and vasopressor agent titration is crucial. In the HACA trial patients were maintained at goal for 24 hours after arrival to the ED, whereas in the Australian trial induction of TH was earlier but maintenance was only for 12 hours. In the TTM trial patients were rewarmed 28 hours after randomization (which roughly corresponded to 24 hours at target temperature). The luxury of having RCTs with different intervals is that it provides a basis for modifying the treatment interval. There has been experience of using longer cooling intervals (up to 72 hours) in conjunction with extracorporeal life support in Japan.²⁷ A case report also details a good outcome in a patient cooled to 33°C for 48 hours postarrest.²⁸ It is possible that like many critical care therapies, the maintenance interval of TTM should

be adjusted on a sliding scale tailored to the particular injury of the patient. However, until more data are available, the consensus opinion is to maintain 24 hours at target temperature.

Rewarming

Although there is no consensus on the optimal rate of rewarming it is recognized that uncontrolled or rapid rewarming can lead to vasodilation, hemodynamic instability, and dangerous electrolyte shifts. There is also limited evidence that rapid rewarming may trigger deleterious cellular injury, obviating the potential benefits of the initial cooling.¹⁵ Herein lies a major advantage in using a TH device, as rewarming can be extremely difficult to control otherwise. Studies have shown that you can safely rewarm between 0.1°C and 0.5°C per hour although the latter may be too rapid for less stable patients. Seizures which are common in the postarrest period tend to occur during rewarming. This author will frequently pause or decrease the rate of rewarming if the patient shows hemodynamic instability or develops seizures until these problems can be addressed. It is likely that the principles of practice listed above are more important when rewarming from a target of 33°C as opposed to 36°C.

Normothermia After Rewarming

It is a common practice to maintain 24 to 48 hours of normothermia (37°C) after rewarming. Rebound hyperthermia is common and the injured brain may be susceptible to further damage. However, despite the logic, there is currently little clinical evidence to support its benefit.²⁷ The only potential harm of normothermia maintenance is that some patients require ongoing sedation to prevent shivering which could delay extubation and neurologic prognostication.

NEUROLOGIC PROGNOSIS

Neurologic prognostication is arguably the most complicated and least well-understood aspect of care revolving around the application of TTM. The medical world is still in its infancies in understanding how temperature management affects healing of the injured brain. Much of what is known about anoxic encephalopathy originated from studies published prior to

the era of TTM. It is crucial to avoid an errant negative prognosis that might lead to withdrawal of care in a patient who could go on to have a good outcome. On the other hand, many individuals would not opt for ongoing care if they were in a persistent vegetative state. Additionally, ongoing care for neurologically devastated patients leads to undue burden on the medical system. Tests should ideally have a zero false-positive rate for determining a poor prognosis, and most of the research has thus been focused on prediction of poor outcomes. Unfortunately, many studies of neurologic tests after TH suffer from the “self-fulfilling prophecy bias.” It is hard to draw conclusions regarding the predictive value of tests that were in turn used as criteria to withdraw care (Table 3–2).

Neurologic Examination: The basic neurologic examination arguably remains the centerpiece for prognostication. Rosetti et al showed that motor response (ability to withdraw from pain and follow motor commands) is often delayed by TH. Absence of motor response on day 3 had a high false-positive rate (24%), and should not be used alone as criteria to withdraw care.³⁰ However, several studies support that the absence of either pupillary or corneal reflexes

TABLE 3–2 Neurologic prognosis.

Reliable Tests (Good Data)	
Examination	Absence of pupil or corneal response at 72 h = bad outcome
SSEP	If bilateral absence = bad outcome
Indeterminate Tests (Limited Data or Less Reliability)	
EEG reactivity	If present associated with good outcome
NSE	Levels > 33 associated with bad outcome
Imaging	Severely abnormal imaging associated with bad outcome
Treatment Refractory Status Epilepticus	If present associated with bad outcome
MSE	If present = bad outcome

at 72 hours postcardiac arrest consistently portends a very poor neurologic prognosis irrespective of the use of TH.^{31,32} A recent meta-analysis suggested that absence of pupillary reflex was a better negative predictor than absence of corneal reflex, and reinforced the lack of reliability of the motor examination.³³

Advanced Testing and Monitoring

EEG

Although there is no RCT showing mortality or neurologic benefit to routine (continuous or spot) EEG monitoring during TTM, EEG helps in the identification and treatment of seizures and also in neurologic prognostication. Seizures are common postcardiac arrest, occurring in 30% to 50% of patients, and may contribute to further brain damage and prolong coma.¹⁵ They are often difficult to detect, due to the high percentage of nonconvulsive status epilepticus as well as the use of sedatives and NMB during TH. However, the abnormal EEG patterns seen after severe brain injury may be difficult to interpret and can be very refractory to treatment. Some believe that treatment refractory nonconvulsive status on rewarming may in fact be “electrical chaos” from a severely injured dying brain and not seizures in the conventional sense. In terms of prognosis, a flat EEG, nonpharmacologic burst suppression, and electrographic status, are all patterns associated with a poor outcome. MSE, bilaterally synchronous twitches of limb, trunk or facial muscles jerks associated with EEG correlate has a well-established association with poor outcome in many forms of anoxic brain injury including cardiac arrest.³⁴ Although this association still largely holds, some reports have suggested that MSE may not be as dismal as a marker in a patient treated with TH.³⁵ The presence of EEG reactivity (an electrographic response to visual, auditory, or painful stimuli) during TH, portends a good outcome while the lack of reactivity portends a bad outcome.

Somatosensory-evoked Potentials

SSEPs are particularly helpful as negative prognostic markers. The median nerve is stimulated electrically at the wrist and a cranial electrode records a response wave called the N20 which reflects stimulation of the somatosensory cortex. The bilateral absence of N20 response on SSEP is possibly the most accurate

predictor of a poor neurologic prognosis, with many early studies showing nearly a 0% false-positive response.³⁶ The 2006 American Academy of Neurology guidelines recommended withdrawing care if there is an absent bilateral N20 response.³⁷ The accuracy of SSEP was again supported by a meta-analysis of over 1000 patients.³² However, there does exist a very small false-positive rate, and there is still a need for caution in interpreting SSEPs in isolation.³⁸

Brain Imaging

There is not enough information to support neurologic prognostication based on head computed tomography (CT) or magnetic resonance imaging (MRI) alone. There are situations in which the imaging is dramatically abnormal and shows for example diffuse cerebral edema, loss of gray-white differentiation, or herniation. However in these cases usually the examination also reflects the extent of injury, so imaging ends up playing a supportive role.

Biomarkers

Neuron-specific enolase is a biomarker of neuronal injury, and there is accumulating evidence of its predictive value during TH. Levels above 33 generally correlate with poor outcome but there have been exceptions.^{39,40}

When to Prognosticate

Caution needs to be exercised against holding to rigid time frames postcardiac arrest. There is wide variability in time to awakening post-TH. In one study the median time to awakening post-TH was 3.2 days but the variability was wide and patients often awaken after 3 days. In this study, 15% of the patients woke more than 72 hours after their arrest.⁴¹ Sedative choices, accumulative doses, and renal function all potentially can impact time to awakening.

SUMMARY OF NEUROLOGIC PROGNOSIS

The TTM trial used a combination of different criteria for prognostication, and this is a well-advised approach. The following were used as criteria to recommend withdrawal of care: MSE plus negative SSEP at 24 hours, GCS motor score 1 to 2 at 72 hours plus negative SSEP, or GCS motor score

1 to 2 at 72 hours plus treatment refractory status epilepticus.⁶ An important general premise is that it is easier to predict who will do very well (eg, the patient who is waking and following commands soon after TH), and easy to predict who will do very poorly (those with lack of brainstem reflexes at 3 days, absent SSEPs). Nevertheless, it is hard to predict long-term outcomes for those who fall in between. It is strongly recommended to take precautions that sedatives are not negatively influencing the neurologic examination post-TH. The lack of pupillary reflexes 3 days postcardiac arrest, the presence of MSE, and the absence of SSEPs all very likely portend an extremely poor prognosis. However, caution should be exercised in using any one test in isolation. Information from imaging, EEG, and neuron-specific enolase levels may be helpful adjuncts, especially in those patients who fall into the gray zone.

Military-Related Injuries

Jamie M. Rand, MD, FACS and Aditya Uppalapati, MD

KEY POINTS

- 1 Military personnel treat injuries which are similar to the civilian population as well as those specific to war and combat.
- 2 Multiple factors influence the five levels of aeromedical evacuation. Patients are moved through the system as quickly and safely as possible with consideration for combat activities and terrain.
- 3 It is important to understand the mechanism of injury. Projectile injuries are influenced by kinetic energy (KE), depth of penetration, and yaw.
- 4 Explosive trauma, resulting in thermal, blast and/or ballistic injury, is the most common mechanism of military-related injury in current conflicts.
- 5 In patients with significant hemorrhage, massive transfusion protocols and viscoelastic coagulation testing guided resuscitation may be helpful. Fresh whole blood transfusion can be an important component in austere conditions.
- 6 Nuclear, biological, and chemical warfare can affect a massive number of individuals. Exposure prevention and decontamination are paramount. Supportive care and exposure-specific management then follow based on patient-specific presentation and factors.

Conflicts in far-reaching and diverse areas of the world have resulted in a myriad of traumatic injuries which health care providers are tasked to treat. Some military injuries are comparable to civilian traumatic injuries, while others are unique to wartime/conflict operations. Unfortunately, with the current state of terrorism, the line between the two is becoming more blurred, making it all the more important for all providers to be aware of what classically have been thought of as “military-related injuries.” In addition to the severity and pattern of injuries, the conflict environment itself adds an additional complexity to providing medical care in these situations. This chapter will provide an overview of the injuries traditionally associated with military operations, as well as highlight operational considerations.

“Lessons learned” from our military colleagues can be lifesaving when applied to disaster situations no matter the location or specific circumstance.

While many surgical advances have been, and are being made, because of the vast experiences of military wartime trauma, many civilian injuries are treated in a similar fashion as military their counterparts. The sheer number of seriously injured in recent conflicts has allowed the military to further evidence-based transfusion practices. For example, the numerous multiple-injured military personnel have allowed for improved mortality in massive transfusion with the creation of 1:1:1 ratio protocols¹ and the addition of tranexamic acid.² In the end, however, these strategies are not significantly different from the massive transfusion protocols in place

in civilian institutions. Similarly, splenic lacerations, whether sustained from a car crash in Missouri or an improvised explosive device (IED) detonating under a tank in Afghanistan, are treated the same. Furthermore, while traumatic brain injury (TBI) may be seen in an increased frequency in current military conflicts, its management is also comparable to its stateside counterpart. The military may be more in tune to the effects of repeat concussions, but the underlying management is the same. This chapter will highlight instances where military trauma varies from civilian trauma.

AEROMEDICAL EVACUATION: FROM THE BATTLEFIELD TO HOME

Before specific injuries are addressed, it is important to understand the basics of how a military member goes from being injured on the battlefield to eventual admission to a hospital in the United States. There are five levels of care described in the military aeromedical evacuation system.³ Unlike the American College of Surgery levels of trauma care, an increase in the military level represents an increase in medical capability.

Level I care is provided by the injured member themselves, other members of their unit, or a medic. This “Self-Aid/Buddy Care” allows for quick control of hemorrhage via pressure dressings, tourniquets, and topical hemostatic agents to stave off early hemorrhagic death. At this level, medical care is frequently complicated by the combat environment. Moving the injured to safety prior to providing medical care can be lifesaving for both the injured as well as the provider.

Level II is the first time a military member will encounter an advanced health care provider. Each branch of service has a slightly different medical team at this level, but it typically either consists of an area support facility staffed with a nonsurgeon advanced health care provider, or a mobile surgical unit which has basic general and orthopedic surgical capabilities. Units at this level typically have a holding capacity of 24 to 72 hours with supplies to support up to 10 operations each day for those 1 to 3 days without being resupplied, with specifics

being dependent on the branch of service. Most of these units are modular in nature and can be supplemented with additional personnel and equipment to further enhance the medical care provided in the tactical environment.

Level III, the theater hospital, is approximately equivalent to a stateside Level III trauma center. This facility is still within the combat zone but has an increased capability, both in terms of the medical/surgical care and holding capacity. For example, Craig Joint Theater Hospital (CJTH), one of the Level III hospitals in support of Operation Enduring Freedom in Afghanistan, has advanced radiology support with computed tomography (CT), magnetic resonance imaging (MRI), and interventional radiology, as well as numerous subspecialty surgical services and 5 to 6 operating room tables. Holding capacity is increased to 44 to 248 beds and to 30 days.

Level IV is a major medical facility, still within the theater of war but outside the combat zone. **Level V** is a major medical center in the United States. These upper echelons have capabilities and staffing similar to civilian hospitals.

Where a patient enters the aeromedical evacuation chain depends on multiple factors, primarily proximity to medical facilities and severity of injury. While most point-of-injury care is provided by Level II facilities, if a member is injured near a Level III facility, then that is where they will receive their initial evaluation. Keep in mind that prior to entering any facility, all patients must be cleared—inspected for unexploded ordinance, booby-traps, or bombs. Safety is paramount while still trying to quickly evacuate the wounded out of the combat zone. For the Afghanistan theater the goal is for patients to reach Level II within 1 hour from time of injury and to be transported to Level III within 24 hours. Transport from the point of injury to Level II is typically by ground or by tactical rotor aircraft. Transport between Levels II and III is also usually via tactical rotor aircraft under the medical supervision of Critical Care Air Transport (CCAT) teams given the smaller and more temporary nature of where these units are located. Transport between Levels III, IV, and V facilities is via fixed-wing aircraft. The goal is to have patients evacuated out to a Level IV facility within 48 to 72 hours from the time of injury. In all

cases, the philosophy is to “get the right patient to the right hospital in the right amount of time,” while preserving the safety and security of all involved.^{3,4}

Spectrum of Injuries

Military-related injuries are comprised of battle and nonbattle injuries, with all possible mechanisms of traumatic injury being represented. In the military setting, these mechanisms of injury are not usually mutually exclusive; one patient may have penetrating wounds, blunt injuries, and blast trauma as well as burns, all from a single incident. Penetrating injury can be from gunshot wounds of varying caliber, knives, or flying projectiles from a myriad of explosive ordinance. Blunt mechanisms include falls, motor vehicle crashes, as well as assaults and sports-related injuries. Burns can occur from accidental or intentional household exposures, fires, explosions, or nuclear/radiation or chemical sources. The most common injury in recent conflicts is a result of explosive trauma, namely IEDs.

Distribution of Injuries

Since the advent of modern warfare, patterns of injury have remained remarkably constant. From World War I to the present, the anatomic distribution of wounds has remained approximately 60% to 70% to the extremities, 15% to the head, and 10% to each the thorax and the abdomen.⁵ Body armor is improving, becoming lighter and more flexible than in previous conflicts. The enhanced capability of body armor likely has contributed to the improved casualty to mortality ratio of 16:1 in Iraq and Afghanistan compared to 2.6:1 in Vietnam.⁶ Furthermore, the most common mechanism of injury is explosive trauma, with IED blasts being more common than gunshot wounds.

Projectiles

Projectiles cause injury through the creation of a permanent cavity as well as a temporary cavity. The permanent cavity is a result of the physical crush injury created by the projectile moving through tissue. The temporary cavity is created by a stretch injury from energy imparted to the tissues as the projectile travels. The permanent cavity is readily apparent at the time of injury, while the temporary cavity may not be as obvious at the initial evaluation. This tissue may initially look viable, but will ultimately become necrotic over time.

The specific characteristics of each type of projectile contribute to the overall damage that is caused. The most important of these characteristics are mass, velocity, depth of tissue penetration, yaw within the tissue, deformation, and fragmentation. KE is directly proportional to the mass and the square of the velocity of the projectile: $KE = \frac{1}{2} \text{ mass} \times \text{velocity}^2$. Thus, for two projectiles with the same kinetic energy, a large slow projectile will directly crush more tissue resulting in a larger permanent cavity, whereas a small fast projectile will impart more of its energy to the surrounding tissues causing more stretch and a larger temporary cavity.⁷

Yaw is defined as the angle between the projectile's long axis and its line of flight. A bullet can yaw during flight prior to encountering a target, or within the target tissue itself. The amount of yaw during flight is relatively inconsequential to the degree of tissue damage, affecting mainly the angle of entry, while the amount of yaw within the tissue contributes significantly to the amount of destruction caused. For example, Figures 4–1 to 4–3 compare the 7.62-mm AK-47 round, 5.6-mm M-16A1 round, and 7.62-mm M-14 or M-60 round with respect to anticipated permanent and temporary cavities.

FIGURE 4–1 Ballistic characteristics of the 7.62-mm round, typical ammunition of the AK-47. (Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.)

FIGURE 4–2 Ballistic characteristics of the 5.6-mm round, typical ammunition of the M-16A1. (Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.)

The M-16A1 round is lighter and faster than the AK-47 or M-14 rounds, with a much higher percentage of fragmentation. It also begins to yaw within a shorter distance, 10 to 15 cm, compared with 15 to 20 cm for the M-14 bullet and 25 cm for the AK-47. The characteristics of the M-16A1 lend to a greater amount of injury compared to the AK-47 or M-14, despite its being a smaller projectile.⁵

Explosive Ordinance

Explosive trauma is currently the most common cause of military-related injury. Depending on proximity to the explosion's epicenter, three distinct types of injuries are encountered: thermal, blast, and ballistic (Figure 4–4).⁵ Those closest to the explosion can be affected by the heat and flames of the explosion resulting in thermal or chemical burns of varying severity. Blast injury can present in three

different classes of injury. Primary blast injury is a result of overpressure from the blast wave itself. All air-containing body structures are at risk of rupture when a victim experiences this sonic shock wave. A ruptured tympanic membrane is the most common injury sustained in blast trauma, followed by pneumothorax and gastrointestinal (GI) perforation. GI perforation can take up to 48 hours to manifest clinical symptoms, so a high index of suspicions is necessary to limit morbidity and mortality from a delayed diagnosis. Ballistic trauma, also classified as secondary blast trauma, is due to flying fragments. These fragments cause injury in a similar manner as projectiles, with permanent and temporary cavities. However, they are typically smaller, less uniform in shape, and impart lower amounts of energy. Ballistic trauma is classified both as secondary blast injury, for projectiles in the environment being thrown

FIGURE 4–3 Ballistic characteristics of the 7.62 NATO round, typical ammunition of the M-14 and M-60. (Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.)

FIGURE 4-4 Type of injury relative to proximity to explosion. (Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 3rd edition. Washington, DC: Department of the Army; 2004.)

by the blast wind, or ballistic injury from fragments of the explosive device itself—either pieces of the explosive’s casing or other objects deliberately placed in the explosive with the intent of causing injury as projectiles. The subtle difference between intentional and unintentional flying pieces of debris allows for ballistic trauma to be classified both with the category of blast trauma and is mentioned separately. Tertiary blast trauma is a result of the explosive force propelling the casualty into surrounding objects. This blunt force trauma results in injuries comparable with other types of blunt trauma, such as motor vehicle crashes or falls. Thus, a patient involved in a significant explosion can sustain burns, overpressure perforations, penetrating trauma, and blunt trauma simultaneously. A detailed thorough systematic evaluation is required to properly identify and address all injuries.

Not only does the type of explosive ordnance influence the injuries sustained, but also where that explosion occurs is of great importance. If the explosion occurs with the patient in a vehicle, it is termed a “mounted” IED event. An explosion triggered by a person outside of an armored vehicle is termed a “dismounted” detonation. In a mounted IED event, an IED or landmine explodes under an armored vehicle (Figure 4-5).⁵ The three forms of blast trauma can still affect the occupants, even though they may still be protected from the outside environment.⁵ Primary blast trauma exists from the blast wave overpressure. Secondary blast trauma exists from objects inside the vehicle becoming projectiles. Tertiary blast trauma exists as occupants collide with

other occupants or portions of the vehicle. Furthermore, toxic gases can be released from the explosive device or the vehicle itself.

In a “dismounted” detonation, the person experiences significant explosive force directly beneath them, with the pressure wave driving debris upwards along fascial planes (Figure 4-6).⁵ Tissue far remote from the most distal site of injury can be damaged from the explosive force, much in the same way as the temporary cavity of a projectile is remote from the permanent cavity.

Given their prevalence worldwide and potential to cause devastating injuries, landmines and other explosive ordnance deserve further consideration. Landmines can be either antipersonnel or antivehicle depending on the intended trigger. Antipersonnel mines can be static, bounding, or horizontal spray.⁵ Static mines explode where they lie once pressure is applied to them, that is, stepped upon. Bounding mines have a separate explosive charge which causes the mine to “pop up” approximately 1 to 2 m prior to exploding. Horizontal spray mines expel fragments in a specific direction. This type of mine can be triggered via tripwire or command detonation. The location of the injuries inflicted depends greatly on the type of antipersonnel mine that is encountered. Static mines cause mainly lower extremity injuries, while bounding and horizontal spray mines can also cause torso injuries.

Another category of explosive ordnance is termed “explosive remnants of war” (ERW). This category is comprised of “unexploded ordnance” (UXO) and “abandoned explosive ordnance” (AXO).

FIGURE 4–5 Pattern of injury from an explosive device under an armored vehicle. (Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.)

FIGURE 4–6 Pattern of injury from a static landmine explosion. (Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.)

Both are unexploded devices. UXOs were deployed as weapons but did not properly explode whereas AXOs were left in an area of conflict without being attempted to be used. While UXO and AXO differ as to why they exist as unattended explosive ordnance in an area of current or former conflict, both types result in similar explosive injuries if detonated. Landmines and ERW are indiscriminant weapons. Personnel or vehicle—man, woman, or child—military or civilian—during an ongoing war or long after the conflict has been resolved—these ordinances affect all the same with devastating results.

According to figures reported by the International Campaign to Ban Landmines, in 2012 there were 3628 casualties of landmines and ERWs.⁸ These casualties were located in 62 countries. Approximately 78% of victims were civilians, with 47% of the civilians being children. While the total number of victims is decreased from 4474 reported in 2011, it is likely that these figures are an underrepresentation of the true morbidity and mortality sustained by these explosive devices. The emotional, physical, and financial toll of these injuries cannot be overestimated.

BLEEDING: WHAT TO GIVE AND HOW MUCH?

As mentioned earlier, combat operations in Iraq and Afghanistan have provided copious amounts of data to help develop improved transfusion strategies. From the analysis of these two wars, as well as large amounts of civilian data, massive transfusion protocols have been developed which provide for earlier transfusion of fresh frozen plasma and platelets, with improved mortality.⁹ The military continues with its civilian colleagues to determine the optimum transfusion strategy. Is it ratio driven? Is it guided by viscoelastic testing—thromboelastography (TEG) or rotational thromboelastometry (ROTEM)—in which whole blood clotting is examined?¹⁰ Military and civilian doctors alike are trying to create rational transfusion strategies which maximally benefit our patients while limiting the inherent risk associated with blood transfusion.

One area where the military differs from its civilian counterparts is the potential use of fresh whole blood. The military often operates in austere

environments in which fractional blood components are not readily available, where supply lines are long, and where the limited supply of blood products, if existent at all, may not be adequate to correct the hemorrhagic shock and associated coagulopathy in the casualties present. In these dire circumstances, fresh whole blood (FWB) is an option.¹¹

FWB provides red blood cells (RBCs), clotting factors, platelets, and fibrinogen—all the components which are required to reestablish hemostasis. The blood is warm, thus not contributing to hypothermia, and is more functional, as clotting is not hampered by the loss of factor or platelet activity through cold storage. Additionally, the RBCs in FWB do not have the lessened oxygen delivery capacity from acquired storage lesions.

However, FWB does have disadvantages. Even with rapid testing for malaria, HIV, hepatitis B, hepatitis C, and syphilis, bloodborne transmission is possible. There is a theoretical increased risk of bacterial contamination given the decreased sanitary conditions inherent to most field conditions. Furthermore, given the chaotic situation in which FWB would be required, the chance of clerical error is increased, compounded by the fact that FWB must be type specific. If more than one person requires FWB, this increased risk for clerical error and a transfusion of incompatible blood is increased even more. Another strictly military consideration is that the donor, also a military member, will have a decreased exercise tolerance for a period of time while the body adjusts to the acute, albeit voluntary, blood loss. It must be remembered that in all situations, the success of the fight trumps any individual. Weakening the remaining fighting force is not a decision to be made lightly.

Nuclear Warfare

Another facet of military-related injuries involves nonconventional weapons. Unfortunately, with the increased activity of terrorist organizations these attacks have been seen in the civilian sector as well. A strong suspicion and good working relationship with the public health sector can greatly assist in determining if a nonconventional attack has taken place and how best to treat those already affected and prevent others from becoming affected.

A nuclear explosion has all the same explosive causes of injury as a conventional explosive—thermal, blast, and ballistic—with the addition of radiation. Radiation exposure requires decontamination prior to being brought into the medical facility, in the same manner as the safety clearance is performed. Triage is first based on a patient's conventional injuries, and then modified based on radiation exposure.¹²

Radioactive particles are classified as alpha, beta, gamma, and neutron. Alpha particles can be shielded by a sheet of paper and are harmful if internalized. Beta particles require a thicker material for shielding such as a layer of clothing or a few millimeters of aluminum. These can cause skin burns and are also harmful if ingested. Gamma particles and neutrons destroy living cells and are only shielded by a few feet of concrete or inches of lead. Radiosensitivity is directly correlated with mitotic rate, as only replicating cells are vulnerable to radiation's effects. Less mitotically active cells are affected only when larger doses of radiation are absorbed. Thus, a patient's symptoms can be used to estimate the amount of exposure incurred. Furthermore, these symptoms and their time-to-onset can be used to predict mortality as the adverse effects of radiation following a fairly consistent pattern.

Radiation exposure is expressed in gray (Gy) or rad. One Gy is equivalent to 100 rad which is equal to 1 J of energy per kilogram.¹³ LD₅₀ is defined as the dose which results in death of half of the people exposed. Exposure of 0.35 Gy can cause transient nausea or headache but is not classified as acute radiation syndrome (ARS). At least 2 Gy are required for ARS to develop.

The hematologic system is affected first with a decline in all cell lines. Radiation exposure affecting only the patient's bone marrow could be latent for 2 to 6 weeks, with the main symptom being fatigue. If there aren't other injuries prompting a medical evaluation, it is possible that medical attention would not be sought, even though it is direly needed. The GI system is affected next. At doses of 6 to 10 Gy, within 2 hours of exposure the patient will have acute-onset cramping abdominal pain, nausea, vomiting, and diarrhea as cells of the GI tract slough. Paradoxically, at doses greater than 10 Gy, nausea is suppressed. Early-onset diarrhea, especially without

nausea, is a particularly poor prognostic sign. Neurologic symptoms, mainly ataxia, seizures, dizziness, and disorientation, suggest an exposure of greater than 10 Gy. Cardiovascular collapse occurs with doses of greater than 35 Gy.¹³

Without supportive care, the LD₅₀ is only 3.5 Gy. Death typically occurs within 60 days as a result of the patient's impaired immunity.¹³ With supportive care, namely fluids, antimicrobials, cytokines, and transfusion, the LD₅₀ increases to approximately 6 Gy. However, these LD₅₀s are based on radiation injury alone. If a patient sustains additional trauma, the LD₅₀ will decrease in accordance with the morbidity and mortality of the other injuries. Furthermore, while some conventional wounds are allowed to heal by secondary intention after repeated debridement, it is important for wounds in irradiated tissue to be closed primarily within 36 to 48 hours. Wounds in irradiated tissue left open for longer than this time frame serve as a source of infection.¹²

Treatment of radiation injury is primarily decontamination to prevent continuing exposure and symptomatic relief. Intravenous fluids are provided for hypotension and increased fluid losses from damaged skin and gastrointestinal cells. Antiemetics provide relief from nausea and vomiting, limiting further fluid losses. Lymphocyte counts can be very useful in determining if a lethal dose of radiation was experienced as well as for directing cytokine therapy. If lymphocyte counts are greater than $1.7 \times 10^3/\mu\text{L}$, a fatal dose is unlikely. Patients with lymphocyte counts less than 300 to 500/ μL can be considered for cytokine supplementation to counteract the radiation's effect on bone marrow. Given these suppressive effects, surgical procedures need to be delayed for weeks if possible, or completed within the first 36 hours. Other supportive measures include potassium iodide to prevent thyroid uptake of radioactive isotopes, chelating agents to bind absorbed metals, and Prussian blue to prevent gastrointestinal absorption of radionuclides.¹²

The evaluation of patients exposed to radiation needs to involve an accurate assessment of those who have a potential for survival. As a general rule, in any military mass casualty situation, if a patient presents with GI symptoms after radiation exposure their chance of survival is low enough and the anticipated utilization of resources is high enough

that they will be triaged to “expectant,” and provided with comfort care measures.

Biological Warfare

Biological warfare also requires close communication between the medical care providers and public health officials. An attack should be suspected in scenarios with an unusual number of illnesses, unusual presentations, or simultaneous outbreaks, especially of diseases not endemic to the area. Weaponized biological agents can be difficult to identify, treat and isolate if a high index of suspicion is not maintained.

Prevention, protection, decontamination, and infection control are key while treating those suspected to be involved in a biological attack. Primary protection through vaccination is one of the most effective ways of minimizing the impact of a biological agent. Vaccination is possible for anthrax, plague, and smallpox. Postexposure chemoprophylaxis is available for anthrax, plague, Q fever, and tularemia. Decontamination, either mechanical via physical removal of the agent or chemical via destruction of the agent, helps to limit spread of the agent from people or clothing. Dilute bleach solutions are also effective for decontamination—either a 0.5% solution for skin or a 5% solution for equipment. Furthermore, ultraviolet (UV) light or heat can be utilized to effectively kill biological agents on inanimate objects.

The type of infection control precautions that are utilized depend on how the biological agent is transmitted. Universal precautions, consisting of hand washing, gloves, gown, eye protection, and masks, are always recommended when it is likely that body fluids may be encountered. When there is concern about transmission via droplets the patient should also be wearing a mask to limit the transmission of these larger particles. Droplet precautions should be instituted for *Bordetella pertussis*, influenza virus, adenovirus, rhinovirus, *Neisseria meningitidis*, and group A *Streptococcus*. Airborne precautions for particles less than 5 μm in size require special surgical masks/respirators. Agents which require airborne precautions include measles, varicella zoster, *Legionella*, disseminated herpes zoster, and tuberculosis. When possible, patients should be kept in private rooms or cohorted with others experiencing similar symptoms.

Table 4–1 lists known potential biological agents, likely symptoms, and appropriate medical management.¹⁴

Chemical Warfare

Toxic chemicals can be used intentionally as weapons, or released unintentionally from industrial accidents. Personal protective gear is required when there is a known threat or attack. Preventing exposure is key. Safe decontamination is paramount when exposure has already occurred. Specific antidotes should be provided as quickly as possible to limit morbidity and mortality. Table 4–2 lists many of the known chemical agents, mechanisms of action, symptoms, and treatments.^{15,16} Surgical procedures can be safely performed after decontamination, but precautions must still be maintained. Double gloves should be worn, instruments should be cleaned with 5% bleach, and removed objects or tissue should be placed in bleach for disposal. Debridement should be performed with a no-touch technique as much as possible.

TRIAGE PRINCIPLES: MILITARY VERSUS CIVILIAN MINDSET

In most scenarios in the US civilian sector, resources are unlimited, personnel are plentiful, and the facility cannot be easily overwhelmed. In the military, the opposite is frequently true. In a mass casualty situation, resource and personnel limitations can force a change in triage principles that can be difficult to enact. As health care providers, we are usually trained to treat patients in a vacuum. Each patient’s viability is based solely on the extent of their injuries. The sickest patient is treated first, but heroic measures will be available to all.

On the battlefield, the goals change. The battle itself remains the overarching goal. “Return the greatest number of soldiers to the fight” is the mantra. The sickest are not always treated first. “Limited resources” literally means that what is used for one patient is not available for the next. “Saving the greatest number of lives” equates to a patient who is deemed expectant in one situation may have been treated further in a less dire situation. Resources may need to be withheld from one so that multiple

TABLE 4–1 **Biological agents, signs/symptoms, and treatments.**

Biological Toxin	Signs/Symptoms	Medical Management
Botulinum	Cranial nerve palsies, paralysis, respiratory failure	Antitoxin, supportive care
Ricin	Fever, cough, dyspnea, arthralgias, pulmonary edema	Supportive care
Bacteria	Signs/Symptoms	Medical Management
Anthrax (<i>Bacillus anthracis</i>)	Fever, malaise, cough, dyspnea, cyanosis	Ciprofloxacin
Plague (<i>Yersinia pestis</i>)	High fever, chills, headache, cough, dyspnea, cyanosis	Streptomycin
Brucellosis (<i>Brucella</i> sp.)	Fever, headache, myalgias, sweats, chills	Doxycycline
Cholera (<i>Vibrio cholerae</i>)	Massive watery diarrhea	Fluids; tetracycline, doxycycline, or ciprofloxacin
Tularemia (<i>Francisella tularensis</i>)	Local ulcer, lymphadenopathy, fever, chills, headache, malaise	Streptomycin
Q-fever (<i>Coxiella burnetii</i>)	Fever, cough, pleuritic chest pain	Tetracycline
Virus	Signs/Symptoms	Medical Management
Venezuelan equine encephalitis (VEE)	Fever, encephalitis	Supportive care
Smallpox	Malaise, fever, rigors, vomiting, headache, pustular vesicles	Investigational antiviral
Viral hemorrhagic fever (VHF)	Facial flushing, petechiae, bleeding, fever, myalgias, vomiting, diarrhea	Supportive care

Reproduced with permission from Borden Institute Army Medical Center: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.

others may live. Mass casualty situations test not only medical skill, but emotional fortitude and resiliency as well.

Triage systems exist to prioritize patients for treatment. One common system utilizes 4 categories: immediate, delayed, minimal, and expectant.¹⁷ The immediate group requires lifesaving surgery or other intervention provided without delay. The delayed group also is likely to require lifesaving surgery; however for this group, surgery can be delayed for a short time without adversely affecting mortality as long as temporizing measures are provided. The minimal group is comprised of minor injuries, the care of which can be provided by nonmedical personnel or be delayed hours to days without adverse effect. Expectant patients are those who have injuries so extensive that the time or resources required

to treat them with the goal of survival exceed that which are available. Expectant patients are provided with necessary pain control and other reasonable comfort measures but lifesaving measures are not pursued.

Another system divides patients into only 3 categories: emergent, nonemergent, and expectant. The emergent group can be thought of as those requiring immediate (within minutes) and urgent (within hours) intervention. Nonemergent patients still require care but do not currently have a threat to life, limb, or eyesight. Expectant patients are again those who, given the circumstances, have non-survivable injuries. No matter which system is utilized, the goal remains the same—to quickly identify which patients need attention first. It is important to remember that triage needs to be repeated.

TABLE 4–2 Chemical agents: mechanism, signs/symptoms, and treatment.

	Mechanism of Action	Signs/Symptoms	Treatment
Nerve agents			
Organophosphates (GA, GB, GD, GF, VX)	Bind acetylcholinesterase	Miosis, rhinorrhea, dyspnea, loss of consciousness, apnea, seizures, paralysis, copious secretions	Atropine, pralidoxime chloride
Vesicants (blister agents)			
Sulfur mustard (HD), nitrogen mustard (HN), Lewisite (L), phosgene oxime (CX)	Alkylating agent, denatures DNA	Skin blisters, airway irritation, conjunctivitis, mucus membrane burns	Decontamination (M291 kit), dimercaprol
Inhalation injury (choking agents)			
Phosgene (CG) (smells like freshly mown grass/hay)	Oxidative stress, neutrophil influx	Throat irritation, pulmonary edema	N-acetylcysteine, ibuprofen, aminophylline, isoproterenol, colchicine, steroids
Chlorine (Cl)	Inhalation burn	Small airway and alveolar irritation, dyspnea	Nebulized steroids, sodium bicarbonate, and beta agonists; mechanical ventilation
Diphosgene (DP)	Airway irritation	Dyspnea	Supportive care, mechanical ventilation
Chloropicrin (PS)	Airway irritation	Dyspnea	Supportive care, mechanical ventilation
Cyanogens (blood agents)			
Hydrogen cyanide (AC) Cyanogen chloride (CK)	Binds to cytochrome oxidase	Seizures, cardiac arrest, respiratory arrest	100% oxygen, activated charcoal, sodium nitrite, sodium thiosulfate
Hydrogen sulfide (smells like rotten eggs)	Binds to cytochrome oxidase	Loss of consciousness, seizures, myocardial ischemia, pulmonary edema, keratoconjunctivitis	Sodium nitrite
Incapacitation agents			
BZ and indoles: atropine, scopolamine, hyoscyamine	CNS effects	Mydriasis, dry mouth, dry skin, increased reflexes, hallucination, impaired memory	Physostigmine

Data from Borden Institute: Emergency War Surgery, 4th edition. Washington, DC: Department of the Army; 2013.

A patient’s condition over time can change, requiring either an elevation in priority if they become more critical or perhaps even a change to expectant if their condition severely deteriorates or the overall situation becomes more dire with an influx of additional casualties. A successful medical operation in a mass casualty situation requires swif , accurate, and repeated triage.

CONCLUSION

In many ways, military-related injuries are treated in very much the same way as their civilian counterparts. However, some differences do exist. T e injuries themselves can differ as military-related trauma can be caused by ordinances not typically encountered in the civilian environment. T e priorities of

treatment may vary as the strength of the remaining fighting force must be maintained. Returning members to the fight is a real consideration. What isn't different is the goal of "getting the right patient to the right hospital in the right amount of time."

Regionalization

Christopher W. Seymour, MD, MSc and
Jeremy M. Kahn, MD, MSc

KEY POINTS

- 1 Regionalization refers to the systematic transfer of high-risk critically ill patients to regional referral centers where intensivists provide high-intensity care.
- 2 Regionalization has several unrealized benefits including the potential to increase survival for critically ill patients through greater use of evidence-based practices and clinical experience with performing of advanced interventions, and shorter time to definitive therapy. Concentrating high-risk, high-cost care for the critically ill also has the potential to reduce overall costs for the health system.
- 3 Potential unintended consequences include the downscaling of critical care capacity at smaller hospitals resulting in reduced ability to provide advanced care in emergencies due to an erosion of clinical skills, inadequate equipment, or familiarity of clinicians with best practice.
- 4 Regionalization may increase intensive care unit (ICU) occupancy or census beyond the capabilities of high-volume referral centers and may also strain the capacity for interhospital transport.
- 5 Barriers to implementation of regionalization include the lack of a strong centralized authority to regulate and enforce the regionalized system; strain on families due to the longer distances to travel for care at referral hospitals, lack of familiarity with physicians/care team at new hospitals, and risks of interfacility transport to new hospital; capacity constraints at large-volume hospitals; and both hospitals' and physicians' potential unwillingness to sacrifice income when patients are transferred to other hospitals for care.
- 6 Special challenges include the need to educate new clinicians in understanding when patients should or should not be treated at referral hospitals, balancing stakeholder needs, and maintaining patient centeredness.

Critical care is usually perceived as a local activity within one hospital—nurses and physicians providing high-intensity care to seriously ill patients within a defined geographic space, without considering the larger health care system outside the hospital. More recently, however, critical care has evolved into a regional activity, one in which intensivists across many hospitals collaborate to provide high-intensity

care to all individuals in an entire geographic area. Large hospitals functioning as “regional referral centers” now routinely provide specialty critical care to the sickest patients,¹ often after long distance interhospital transfers,² while the threats of pandemics and natural disasters are forcing hospitals to align within regions in a state of critical care preparedness.³ Moreover, governmental agencies

will soon require that regional critical care services not only be coordinated but also be accountable—that is, hospitals and regions will have to show that they are capable of effectively providing high-quality critical care to all patients in need.⁴ Such is the mandate of the United States Patient Protection and Affordable Care Act—which seeks to link payment to quality, coordinated care, and more efficient health care delivery at the level of the system, not just the individual provider.

Many factors might explain the shifting paradigm in the delivery of critical care. First, critical care is expanding and now accounts for more than \$80 billion per year in US health care costs, almost 1% of the gross domestic product (GDP).⁵ These extreme financial burdens and the increasing volume of patients demand attention to more efficient care strategies in critical illness. Second, an expanding information technology system allows hospitals to share clinical information rapidly and securely, enabling more effective cross-hospital care coordination.⁶ Third, interfacility transport is increasingly safe over long distances, even for the critically ill.^{7,8} Fourth, a limited supply of trained intensivist physicians in the United States makes it difficult to match intensivist supply with the increasing demand for critical care, necessitating system-level approaches to matching supply and demand.⁹

Additionally, and perhaps most importantly, health care stakeholders increasingly recognize that hospitals vary widely in their capabilities and overall quality of critical care.¹⁰ Not all hospitals are capable of providing 24-hour trauma care, emergency stroke assessments and treatment, emergency surgery, advanced interventional cardiology, or specialty medical services like continuous renal replacement therapy or extracorporeal membrane oxygenation (ECMO), as there are substantial fixed costs to keep these critical care services “at the ready.” The few hospitals that do provide these services are not readily accessible to the general US population.¹¹

This chapter will review the concept of regionalization, a regional care coordination strategy designed to address these problems. Under critical care regionalization, high-risk patients would be systematically transferred to regional referral centers. The chapter will outline conceptual models for

regionalization, review the existing evidence, and provide practical guidance for clinicians who will increasingly be required to develop, manage, and practice regionalization in their health care system. Of note, regionalization is only one of several approaches to regional critical care coordination.¹² Others include ICU telemedicine and community-based education. These topics are discussed elsewhere in this textbook. Regionalization should be viewed as complementary to these other approaches, to be undertaken in concert as part of a holistic, regional approach to critical care.¹³

WHAT IS MEANT BY “REGIONALIZATION”?

Regionalization is the systematic transfer of high-risk critically ill patients to regional referral centers. A regionalized critical care system requires the following four components:

- a. A method to define regions, either by geography or by political boundaries
- b. A method to identify hospitals by their critical care capability
- c. A strategy to triage patients to designated referral hospitals
- d. A regulatory body to manage and provide oversight for the system

Each of these individual components are important for different reasons. Without a consensus-based definition for regions, it will be impossible to hold providers accountable for their coordinator efforts or to enact local legislation to support the process. Without an objective method to stratify hospitals based on capability, it will be impossible to identify regional critical care centers. Without a valid approach to triage, it will be impossible to get the right patients to the right hospitals. And without a regulatory body to oversee the system, it will be impossible to effect meaningful change.

The care for many diseases and syndromes in the US health care system is already organized in regionalized systems based on these four components. These include time-sensitive conditions that are similar to those commonly cared for in ICUs. Most notably, patients with traumatic injury are cared

for in a mature regional system. Early trauma systems grew out of advances in emergency medicine and triage made during the Vietnam conflict. Triage was followed by extensive advocacy by professional societies that recognized the potential for improved outcomes by centralizing care for seriously injured patients.¹⁴ In addition, a broad evidence base establishes that injured patients receiving care in a trauma center are more likely to experience improved outcomes as a result of their injury than similar patients receiving care in a nontrauma center.¹⁵ These systems continue to be evaluated for their ability to improve patient-centered outcomes.

Other syndromes or diseases that are considered for regionalization include ST-segment elevation myocardial infarction (STEMI),¹⁶ neonatology,¹⁷ stroke,¹⁸ and cardiac arrest, although formal regionalization for these areas is far less prevalent than for trauma. Many features of these conditions make them amenable to centralized care, including the following:

- a. The high risk for an adverse outcome
- b. The time-sensitive nature of the conditions
- c. The extensive infrastructure and stand-ready costs for effective 24-hour care
- d. Established volume-outcome relationships that suggest that outcomes might be improved by centralizing care at high-volume centers¹⁹

Based on these examples in comparable syndromes and a broad conceptual foundation, critical care regionalization is supported by several multidisciplinary stakeholder groups.²⁰ In fact, there are calls for the implementation of regionalized care for critical care in general as well as for the specific disease states with a high-likelihood of critical illness (eg, acute myocardial infarction [MI], acute stroke, high-risk surgeries, and out-of-hospital cardiac arrest).²¹ In the United States, these calls were followed on by proposed legislation in the US Congress that seeks novel methods of critical care delivery for highest-risk patients.²²

POTENTIAL BENEFITS

Regionalization has several unrealized benefits, including the potential to increase survival for critically ill patients. If sickest patients are rapidly triaged

to centers of excellence, several time-sensitive evidence-based practices could be provided, including thrombolysis for stroke,²³ targeted temperature management after cardiac arrest,²⁴ or quantitative fluid resuscitation for septic shock.^{25,26} High-volume centers may also facilitate evidence-based practices, which although not time sensitive, may be more thoroughly delivered at referral centers with regular use. These might include low-tidal volume ventilation for acute lung injury,²⁷ daily interruption of continuous sedative infusions,²⁸ and ECMO for severe acute respiratory failure.²⁹ Improved outcomes at higher-volume centers (ie, volume outcome relationship) may derive from a variety of factors. These could include on-call resources for advanced procedures (eg, ECMO), greater clinical experience with performing and management of advanced interventions, or shorter time to definitive therapy. Although untested in a randomized trial, the concentration of these critically ill patients at centers of excellence may improve critical care outcomes.

Regionalization could also have financial implications for critical care. ICUs exhibit economies of scale. In other words, the greater the throughput of patients in an ICU is accompanied by lower per unit costs.³⁰ Because most hospital costs are fixed, higher-volume hospitals share those fixed costs over more patients, improving overall efficiency. For example, high-cost equipment and personnel like the oxygenator and perfusionists for an ECMO machine may be too expensive for a small community hospital if only used occasionally each year. However, if a referral center uses ECMO every day, the costs of that machine and personnel are spread over many patients, reducing the per patient costs. In this way, concentrating high-risk, high-cost care for the critically ill has the potential to reduce overall costs for the health system.

In addition, regionalization may have subtle benefits to the prevalent disparities in the delivery of critical care. Recent evidence suggests that certain critical care services are unequally distributed across racial and ethnic groups, as well as ability to pay, and these differences may impact patient outcomes like 30-day mortality.³¹ In fact, transfers of patients for common critical illnesses like sepsis or complaints like chest pain may be less common among the uninsured.³² Such disparities by race, ethnicity, or

insurance status could be mitigated through structured regionalization in which transfers to regional referral centers are determined by explicit criteria based on illness severity, rather than on implicit criteria that are more subject to bias.

POTENTIAL UNINTENDED CONSEQUENCES

The potential clinical and economic benefits of regionalization may be offset by a number of potential unintended consequences.³³ First, the upscaling of critical care capacity at referral hospitals may require the downscaling capacity at others. Downscaling may result in a reduced ability of small hospitals to provide advanced care in emergencies due to an erosion of clinical skills, inadequate equipment, or familiarity of clinicians with best practice. For example, under a regionalized scenario smaller hospitals may see fewer cases of septic shock. Septic patients receiving care in these hospitals may be subject to increased morbidity as a result.³⁴ Although regionalization may benefit patients up-triaged to regional referral centers, it may harm patients who remain at smaller community hospitals. Regionalization may also extend harm to other patients, as many high-margin medical services such as oncology and cardiac surgery require high-quality ICUs. The downscaling of critical care may force these hospitals to abandon other profitable programs that require intensivists to care for their patients, limiting access to these services in rural communities.

Second, regionalization of the critically ill may increase ICU occupancy or census beyond the capabilities of high-volume referral centers. Many large academic medical centers are operating at high capacity, and are under pressure to expand with rising number of critically ill patients. If ICU occupancy is at capacity limits, access to ICU beds may be reduced for other patients—potentially worsening their outcomes. Indeed, boarding critically ill patients in the emergency department or in ICUs unequipped to care for specialty cases is associated with higher mortality,^{35,36} a situation that may increase under regionalization. As well, Gabler et al found that across 155 US ICUs in more than 200,000 patients, small increases in ICU strain were

associated with 2% to 7% increase in the odds of mortality.³⁷

Regionalization may also strain our capacity for interhospital transport, or the ability to move patients from small hospitals to referral centers. Multiple studies demonstrate that long-distance transfer of critically ill patients by both ground or aeromedical transport is both feasible and safe.³⁸ However, these observations occur under the existing system, which likely limits transfers only to those most likely to survive. The capacity of this system to accommodate a larger volume of patients, sicker patients, and patients earlier in their hospital course in the setting of predefined transfer criteria, has not been empirically tested.

Despite the economy-of-scale rationale for regionalization, regionalization may increase health care utilization in some scenarios, leading to higher costs. Unforeseen costs may include flight or transport costs to a new facility, and added fixed costs to oversee and regulate the coordinated system. Many trauma systems struggle with issues of costs and cost-effectiveness, in particular how to manage stand-ready costs for unpredictable and unscheduled, high-priced patients. With even more general critically ill patients than trauma, it is likely that a regionalized critical care system will have multiple competing financial implications at both the referral and referring hospitals.

CLINICAL EVIDENCE

Little empiric data support regionalization for critical care. As previously mentioned, regionalization is indirectly supported by the existence of volume-outcome relationships and successful implementation of regionalized systems in trauma and neonatal care.³³

Additional indirect evidence for regionalization of the critically ill derives from the conventional ventilatory support versus extracorporeal membrane oxygenation for severe adult respiratory failure (CESAR) trial. In this United Kingdom-based, multicenter trial, 180 patients with severe but potential reversible acute respiratory failure were randomized to receive conventional management or referral to a specialty center for consideration for ECMO. Because of the intent-to-treat analysis and

that only 75% (N = 57 of 90) assigned to ECMO centers actually received ECMO, the study has findings that speak toward referral center care as opposed to just ECMO. In fact, those referred experienced a 16% increase in months without disability, and 0.03 increase in quality-adjusted life-years (QALYs) at 6-month follow-up.

An additional study during the 2009 H1N1 influenza pandemic revealed differences in outcome among acute respiratory distress syndrome (ARDS) patients who were and were not referred for ECMO at 4 adult ECMO centers in the United Kingdom.³⁹ Using multiple strategies to account for patient differences, this observational study found between 22% and 29% reduction in mortality for H1N1-related ARDS patients referred to ECMO centers. Randomized trials of this regionalization strategy are particularly challenging from ethical, logistic, and practical barriers—and even more so during pandemics. Yet this observational study provides strong observational evidence of the power of transfer to a regional referral center to save lives in critical illness.

Finally, indirect support derives from simulated data which evaluated the impact of regionalization for nonsurgical patients in the United States receiving mechanical ventilation.⁴⁰ Therein, the authors analyzed hospital discharge data from 8 US states in which 50% of mechanically ventilated patients received care in ICUs with very low admission volumes. By simulating the transfer of those patients to high-volume centers and assuming a mortality benefit similar to prior volume-outcome studies, the authors found that transferring 16 patients would prevent one death. Trade-offs were small for patients, and transfer distances were relatively small for most patients in urban areas. The study concluded that regionalizing care was feasible and might result in a significant mortality benefit for many who are critically ill.

This study has many limitations. The authors assumed that patients transferred to regional referral centers would receive the same mortality benefit as patients originally admitted to those centers. Additionally, the study assumed a perfect triage model whereby all eligible patients were successfully triaged to a regional referral center. In reality, triage of critically ill patients is a complex decision informed by severity of illness, insurance status, distance,

and preexisting relationships between clinicians (both referring and receiving) and patients. And as shown in trauma, where triage criteria are relatively standardized and objective,⁴¹ optimal triage that is adherent to guidelines is difficult to achieve. In critical care, triaging patients to referral centers may be more challenging, as there are no commonly accepted strategies to assess who would benefit most at referral centers, nor agreement among providers. Several strategies are under development that may inform critical illness triage, both at the beginning of critical care in the ambulance and after initial stabilization at referring hospitals.⁴²

BARRIERS TO IMPLEMENTATION

The implementation of regionalized critical care faces several key barriers (Table 5–1). As identified in a 2009 survey of ICU physicians, one such barrier is the lack of a strong centralized authority to regulate and enforce the regionalized system.⁴³ No central health authority exists in the United States to oversee a regionalized system—and even trauma regionalization pieces together multiple authorities across many regions. Central oversight has been proposed for cardiac arrest centers but has been difficult to adopt and implement.⁴⁴ Competition among

TABLE 5–1 Barriers for stakeholders in the development of regionalized care systems for critical care.

Barriers for hospitals
Potential to decrease quality of care at smaller hospitals
Financial implications for hospitals and physicians
Potential to overwhelm census and capacity at large hospitals
Barriers for patients
Long(er) distances to travel for care at referral hospitals
Lack of familiarity with physicians/care team at new hospitals
Risks of interfacility transport to new hospital
Barriers for the system
Absence of criteria to determine if patients should be transferred
No standardized consensus criteria to designate referral center
No central authority to oversee and regulate the system

US hospitals may lead to additional barriers for criterion-based categorization of hospitals as critical care “centers of excellence.” Some countries such as the United Kingdom, Canada, and Australia have public health systems and regional health authorities capable of regulating a regionalized critical care system, however even in these countries hospitals may resist efforts to dictate the services they can provide.

Families may also be strained by regionalized critical care. Some families may be forced to travel long distances to receive critical care, often by unfamiliar clinicians in new hospitals. In a simulation study of regionalized mechanically ventilated patients,⁴⁰ the increase in distance from moving patients to referral centers was 8.5 mi. As such, the regionalized system may therefore place undue burden on families and compromise the patient-physician relationship, leading to adverse consequences such as cognitive and emotional dysfunction among family members.⁴⁵ As shown in other conditions like pancreatic cancer,⁴⁶ patients and families may be willing to accept a higher risk of death if it means receiving care closer to home. This may be more prevalent in patients less likely to survive the hospitalization.

Many other barriers limit regionalization. These include capacity constraints at large-volume

hospitals, the difficulty in accurately identifying patients in triaging patients for transfer in a consistent, reliable manner, and both hospitals’ and physicians’ potential unwillingness to sacrifice income when patients are transferred to other hospitals for care. And crucial to any regionalized system is the efficient ability to move patients between hospitals. This requires both aeromedical and ground emergency medical services personnel to be trained, available, and compensated for participation in critical care transport.⁴⁷

STRATEGIES FOR IMPLEMENTATION

The effective implementation of regionalized critical care will require both intelligent system design and coordination among stakeholders. First, regional systems can be designed around either a traditional hub-and-spoke model or a model with multiple disease-specific referral centers (Figure 5–1). The relative merits of each of these approaches are unknown. Second, policy makers must explicitly define the methods to identify regional referral centers. In cardiac arrest, proposed criteria include (1) capability and timeliness of advanced

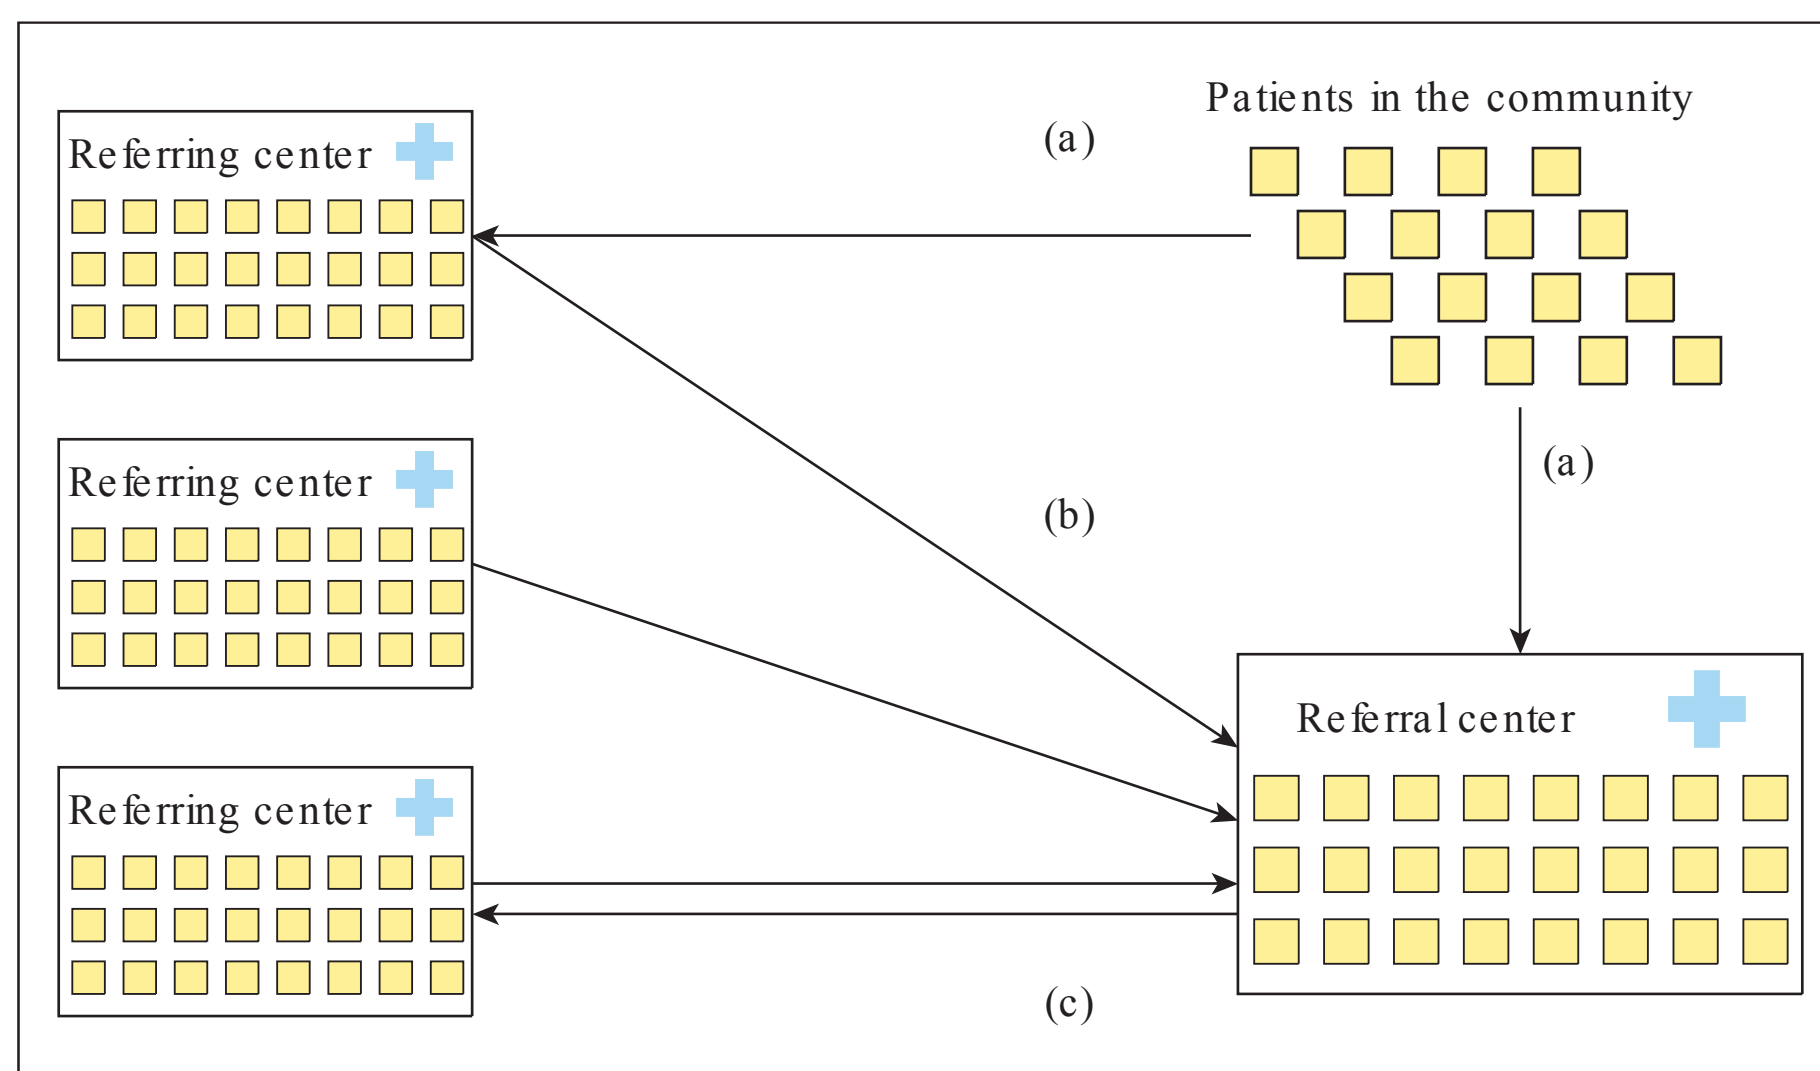

FIGURE 5–1 Schematic of regionalized critical care system where patients can be routed on a variety of paths: (A) admission to referring or referral hospitals from the community, (B) Up-triage of higher acuity patients from referring to referral hospitals, or (C) Down-triage of lower-acuity patients to referring hospitals.

procedures, (2) monitoring and reporting of outcomes, (3) aligned with others in the system of care (eg, emergency medical service [EMS] and emergency department [ED]), and (4) participation in certification programs. Potential structural criteria for referral center certification include intensivist physician staffing and the availability of definitive surgical, coronary, and cardiac care, among others (Table 5–2).^{15,29,48–53} Certification as a regional referral centers should be voluntary to ensure maximal buy-in, yet certification should be regulated by existing governmental bodies in order to ensure that the number and location of regional referral centers best meet population needs.

In addition, stakeholders need to standardize the method to identify patients in need to transfer to a regional care center. Transfer criteria are more objective and reliable among ST-elevation MI patients, but may be more difficult to establish for the medical critically ill. It is essential that these criteria be objective to avoid subjective and arbitrary decisions that impact hospital economies or facilitate gaming of the system. The overall goals include improving access to best care but also delivering best care in an equitable fashion. Such equity may be harmed if some regions are

overserved by regional centers and other regions are underserved.

In practical terms, the implementation of a regionalized system requires dedicated, coordinated efforts by participating clinicians and critical care policy makers. Such broad stakeholder support is essential, with leadership needed from professional societies to develop evidence-based standards for hospital certification, and governmental accreditation bodies those are in the best position to enforce those standards. Regionalization will also require demonstration products supporting both feasibility and effectiveness. Given the large-scale system change that is mandated through regionalization, it is unlikely that we can proceed until initial studies demonstrate improvements in patient-centered outcomes.

THE ROLE OF INTENSIVISTS

Intensivists will play a major role in a regionalized system. In fact, many intensivists in large health systems participate in ad hoc regionalization already. If critical care is further regionalized in a systematic fashion, it will occur as an inclusive system, whereby many hospitals are capable of providing some level of critical care but the sickest patients are transferred to higher levels. In contrast, an exclusive system occurs when only some hospitals provide critical care, and initial triage is performed by emergency department and EMS personnel prior to hospital admissions. Such a distinction has great implications for emergency care clinicians who may not be positioned or available to perform this triage. In addition, intensivists will also be called upon to inform overall system design, including the outcomes by which integrated critical care systems will be evaluated for quality and outcomes. Thus, intensivists will take an active role in the development of these regional systems, and challenged to maintain a patient-centered view during the process.

SPECIAL CHALLENGES FOR REGIONALIZATION

The gap between evidence and critical care practice, substantial variation in critical care across hospitals, and the growing intensivist workforce crisis in the

TABLE 5–2 Candidate structural characteristics and services of a regional referral center for critical care.

Personnel availability Perfusionists for extracorporeal membrane oxygenation (ECMO) 24-h neurosurgeons 24-h percutaneous transluminal coronary angioplasty
Certifications in other specialties Stroke center Level I trauma center
Advanced procedures Percutaneous transluminal coronary angioplasty for diagnosis and treatment Renal replacement therapy Extracorporeal membrane oxygenation
Structural characteristics Multidisciplinary rounds for all intensive care patients All ICUs staffed by trained intensivists under closed or mandatory consult model

United States are unlikely to go away soon. As such, the need for studying more efficient, cheaper critical care strategies is likely to expand. Consequently, there are special challenges we must face in the reorganization of critical care.

Educating New Clinicians

Traditional medical education emphasizes individual patient care at the bedside, with lessons on the pathophysiology of disease tightly linked to the patient history and physical examination, a focus on communication with the patients, ethics, and professionalism in response to new challenges faced by doctors. Yet, this multidisciplinary curriculum does not prepare trainees to practice in the fully integrated health system of the future. This health system provides care across regions using a combination of technological, physical approaches, and shared resources. The Accreditation Council for Graduate Medical Education has been proactive in this regard by incorporating “systems-based practice” as a core competency critical care fellowship education. To ensure a prepared workforce we must continue to emphasize a system’s view in the education of our future intensivists. This will include an understanding of when patients should or should not be treated at referral hospitals.

Balancing Stakeholder Needs

If critical care is organized into a regionalized system, competing stakeholder needs will require careful balancing. The relevant stakeholders in critical care include community physicians, academic physicians, other clinicians, hospitals, governmental agencies, EMS personnel who transport patients, and health care purchasers. All these stakeholders have different needs and incentives that do not always align. For example, regionalization may require community physicians to sacrifice autonomy, patients, and procedures in order to achieve greater health care quality. Conversely, hospitals that receive patients from smaller centers may operate with high census, straining staff, and resources. A balance of stakeholder views and appropriate “buy-in” is a major practical hurdle to future implementation studies.

Maintaining Patient Centeredness

Most importantly, the patient should be at the center of future proposals for regionalized care. Patients have shown that they will not always choose longer distances for specialized care,⁴⁶ and we must not forget to consider patient and family wishes when we suggest transferring critically ill patients. In fact, many important components of multidisciplinary critical care, including pastoral services, end-of-life care, and family presence may be more challenging when far from home.

In the end, we face a growing challenge to maximize health care value, whereby the greatest benefit is achieved for the greatest number of people in the most efficient manner. Mindful of the importance of the patient, regionalization is one strategy to accomplish this goal.

Pre-ICU Syndromes

George Lominadze, MD; Massoud G. Kazzi, MD and
Ariel L. Shiloh, MD

KEY POINTS

- 1 A demand on the limited number of ICU beds requires more acute and complex patient care to be delivered on the general wards, outside of the ICU.
- 2 Rapid response systems are designed to address this goal and rapid response teams (RRTs) or medical emergency teams (METs) have become increasingly prevalent in the US hospital systems as the means to intervene in the care of hospitalized patients with acute clinical deterioration.
- 3 The identification of prearrest physiology such as abnormal vital signs, or a sudden change in vital signs, can help identify clinical deterioration minutes to hours before a serious adverse event, often providing sufficient time to deliver an intervention.
- 4 The Society of Critical Care Medicine has identified the 5 principal admitting ICU diagnoses as respiratory failure or insufficiency, the need for postoperative management, ischemic heart disorders, sepsis, and decompensated heart failure. The correlating rapid response triggers for these conditions are often identified as hypotension, altered mental status, and respiratory distress.

PRE-ICU SYNDROMES: RECOGNITION AND RAPID RESPONSE

Rapid Response Teams

The Joint Commission's National Patient Safety Goals, directs health care providers to improve the identification of clinical deterioration in hospitalized patients and select "a suitable method that enables health care staff members to directly request additional assistance from a specially trained individual(s) when the patient's condition appears to be worsening."¹

Rapid response systems are designed to address this goal and RRTs or METs have become increasingly prevalent in the US hospital systems

as the means to intervene in the care of hospitalized patients with acute clinical deterioration.^{2,3} RRTs are called to evaluate and treat not only the patients who had a cardiorespiratory arrest (for which traditional code teams exist), but also to assess patients who are having symptoms indicative of an impending cardiorespiratory or neurologic deterioration, thus supplementing traditional code teams in scope and frequency of response.²⁻⁵ RRTs may be called for signs of clinical deterioration, such as vital sign abnormalities, arrhythmias, dyspnea, and altered consciousness. A demand on the limited number of intensive care unit (ICU) beds requires more acute and complex patient care to be delivered on the general wards, outside of the ICU.⁶

Rapid Response Activation

The RRT team is activated in instances of perceived patient deterioration and recognition of clinical deterioration. RRT calls are most commonly prompted by cardiorespiratory and neurologic symptoms identified by hospital staff (clinical and nonclinical) or even family members.

The identification of prearrest physiology such as abnormal vital signs, or a sudden change in vital signs, can help identify clinical deterioration minutes to hours before a serious adverse event, often providing sufficient time to deliver an intervention.⁷⁻⁹ Indeed, diurnal variation of RRT activation rates generally correlate with the timing of caregiver visits.¹⁰ Delays in provider notification and failure to seek help in a timely manner by ward personnel can also contribute to suboptimal outcomes and increased mortality even when RRT systems

are in place.^{11,12} Providing objective criteria as a guide for the activation of RRT improves utilization of the RRT systems.

Studies have searched for the minimal criteria for RRT activation. Universally, vital signs monitoring and evaluation of mental status is reproducible and effective.¹³ Trigger systems that rely on these parameters alone are known as single and multiple parameter systems based on the number of physiologic criteria included (Figure 6–1). Continuous vital sign monitoring is not feasible for non-ICU patients; so the optimal frequency of vital sign monitoring is patient dependent and difficult to generalize to all patient populations.¹⁴

In a review of current early warning systems for recognizing and responding to clinically deteriorating patients, relevant policies were examined to determine the vital sign parameters and trigger

thresholds that activate RRT. Most hospitals scored respiratory rate, heart rate, systolic blood pressure, and consciousness level as triggers, and some additionally scored urine output, oxygen saturation, and need for oxygen administration. The thresholds for classifying the values as abnormal varied between the hospitals and were chosen seemingly arbitrarily based on local preferences and expertise.¹⁵ A study of 400 rapid response calls at a large Australian teaching hospital found the most common reasons for RRT activation to be hypoxia (41%), hypotension (28%), altered consciousness (23%), tachycardia (19%), increased respiratory rate (14%), and oliguria (8%). Infection, pulmonary edema, and arrhythmias featured prominently as underlying morbidities and were thought to be responsible for 53% of all triggers for RRT calls.¹⁶

Traditional ICU scoring systems, such as the sequential organ failure assessment (SOFA) score or the multiple organ dysfunction score (MODS)

which are used to predict ICU mortality have been adopted by some institutions as markers for clinical deterioration of non-ICU patients.

The National Early Warning Score Design and Implementation Group (NEWSDIG) in the United Kingdom developed the VitalPac Early Warning Score (ViEWS), a validated scoring system for the early detection of clinical deterioration and prediction for cardiac arrest or need for ICU transfer. The aggregate weighted system scores physiologic parameters to determine the need for more frequent monitoring or ICU-level care. The parameters include respiratory rate, oxygen saturation, supplemental oxygen use, temperature, systolic blood pressure, heart rate, and level of consciousness. Higher scores indicate the need for more frequent reassessment and higher level of care (Figure 6–2A–C). Similar scoring systems such as the cardiac arrest risk triage (CART) have been

National early warning score (NEWS)

Physiological parameters	3	2	1	0	1	2	3
Respiration rate	≤ 8		9-11	12-20		21-24	≥ 25
Oxygen saturations	≤ 91	92-93	94-95	≥ 96			
Any supplemental oxygen		Yes		No			
Temperature	≤ 35.0		35.1-36.0	36.1-38.0	38.1-39.0	≥ 39.1	
Systolic BP	≤ 90	91-100	101-110	111-219			≥ 220
Heart rate	≤ 40		41-50	51-90	91-110	111-130	≥ 131
Level of consciousness				A			V, P, or U

The NEWS Score Initiative flowed from the Royal College of Physicians' NEWS Development and Implementation Group (NEWSDIG) report, and was jointly developed and funded in collaboration with: The Royal College of Physicians, The Royal College of Nursing, The National Outreach Forum, and NHS Training for Innovation

The national early warning score (NEWS) thresholds and triggers

New scores	Clinical risk
0	Low
Aggregate 1-4	
RED score* (Individual parameter scoring 3)	Medium
Aggregate 5-6	
Aggregate 7 or more	High

The NEWS trigger system aligned to the scale of clinical risk

*RED score refers to an extreme variation in a single physiological parameter (ie a score of 3 on the NEWS chart, coloured RED to aid identification and represents an extreme variation in a single physiological parameter). The consensus of the NEWS Development and Implementation Group (NEWSDIG) was that extreme values in one physiological parameter (eg heart rate ≤ 40 beats per minute, or a respiratory rate of ≤ 8 per minute or a temperature of $\leq 35^{\circ}\text{C}$) could not be ignored and on its own required urgent clinical evaluation.

developed using logistic regression. The CART score has been validated for in-hospital cardiac arrest (AUC 0.84) and the need for ICU transfer (AUC 0.71).¹⁷ Over 100 track and trigger systems have been developed in recent years, making it extremely difficult to accurately compare and validate them with each other.

More recently, prediction models using vital sign, demographic, location, and laboratory data in electronic health records have been developed as early warning systems for adverse outcomes on the wards. The models are able to calculate a risk score based on computerized data to alert caregivers with automated, real-time, information regarding patient deterioration. Compared to manually calculated systems, automated systems are the least error prone to calculation errors and are the least labor intensive. Although potentially quite useful, these automated scoring systems should not be regarded as the

sole solution for detecting patient deterioration; the systems are highly sensitive and may overestimate clinical deterioration or need for higher level of care. Rather, their use could be an adjunct to alert staff to the need to further clinically assesses patients.¹⁸

A large systematic review demonstrated that implementation of single parameter triggering systems alone are unlikely to improve hospital survival, and that there was only weak evidence in the reduction of cardiac arrest. In contrast, aggregate weighted scoring systems improved hospital survival and reduced both unexpected ICU admission and cardiac arrest rates.¹⁹

Outcomes

Typical call rates are 20 to 40 per 1000 admissions and the in-hospital mortality of such patients is 24% to 34%.^{3,20} Although the MERIT study, a multicenter, cluster-randomized, controlled trial of RRT systems

Outline clinical response to NEWS triggers

News score	Frequency of monitoring	Clinical response
0	Minimum 12 hourly	<ul style="list-style-type: none"> • Continue routine NEWS monitoring with every set of observations
Total: 1-4	Minimum 4-6 hourly	<ul style="list-style-type: none"> • Inform registered nurse who must assess the patient; • Registered nurse to decide if increased frequency of monitoring and/or escalation of clinical care is required;
Total: 5 or more or 3 in one parameter	Increased frequency to a minimum of 1 hourly	<ul style="list-style-type: none"> • Registered nurse to urgently inform the medical team caring for the patient; • Urgent assessment by a clinician with core competencies to assess acutely ill patients; • Clinical care in an environment with monitoring facilities;
Total: 7 or more	Continuous monitoring of vital signs	<ul style="list-style-type: none"> • Registered nurse to immediately inform the medical team caring for the patient—this should be at least at specialist registrar level; • Emergency assessment by a clinical team with critical care competencies, which also includes a practitioner/s with advanced airway skills; • Consider transfer of clinical care to a level 2 or 3 care facility, i.e. higher dependency or ITU;

failed to demonstrate that implementation of RRTs led to a decrease in cardiac arrests, ICU admissions, or unexpected deaths;²¹ post hoc analysis showed a significant improvement in outcomes when the data were analyzed in an as-treated model rather than an intention-to-treat model.²² Further single-center trials also point to improved outcomes in hospitals that implemented RRTs.²⁰ A meta-analysis of 18 studies reviewing the effectiveness of RRT systems in acute care settings demonstrated that the implementation of RRTs is associated with reduced rates

of cardiorespiratory arrests outside of the ICU with relative risk reduction of 33%.²³ In addition, a retrospective study of nearly 6 million admissions over a 10-year period showed the presence of a hospital RRT system for more than 2 years was associated with 0.14% absolute risk reduction of in-hospital mortality across a major metropolitan health network, which translated to 56 lives saved per year in a hospital with 40,000 admissions per year.²⁴ Mortality benefits after the introduction of RRTs are not always immediate and may take time to become apparent.

In general, triage decisions based on rapid response evaluation regarding transfer of patients to the ICU or general ward care seem to be appropriate. In a large study, 12.7% of patients that had RRT activation required repeat RRT activation and of those around 80% were transferred to the ICU. A total of 0.4% died within 24 hours of the index RRT activation, with half of the mortalities occurring as unexpected cardiac arrests on the wards, while the other half occurred in the setting of ICU care, or palliative care, after the repeat RRT call.²⁵

Inappropriate triage and disposition of unrecognized critical illness at the time of initial admission are contributing factors to unfavorable patient outcomes. Indeed, RRTs occurring early in hospitalizations (hospital days 0 and 1) constitute approximately 27% of all calls and partially reflect suboptimal triage decisions.¹⁰

Team Composition

The composition of the RRT can vary significantly based on the hospital system and available resources.²⁶ Teams are often comprised of multidisciplinary staff that may include critical care medicine fellows or attendings, internal medicine housestaff or hospitalists, respiratory therapists, physician assistants, nurse practitioners or an ICU nurse. Studies evaluating ideal team composition are sparse.²⁷ It is difficult to assess the optimal team composition and subsequent outcomes due to the amount of variation that exists. While it has been shown that response teams led by attending intensivists and senior medical residents had similar outcomes, teams led by nurses alone had equivocal outcomes.¹⁹

PRE-ICU SYNDROMES: ASSESSMENT AND TREATMENT

The Society of Critical Care Medicine has identified the five primary ICU admission diagnoses as: respiratory system diagnosis with ventilator support, acute myocardial infarction, intracranial hemorrhage or cerebral infarction, percutaneous cardiovascular procedure with drug-eluting stent, and septicemia or severe sepsis. Additional diagnoses that often require ICU admission include: toxins, heart failure, arrhythmias, renal failure, and gastrointestinal hemorrhage.²⁸

The correlating rapid response triggers for these conditions are often identified as hypotension, altered mental status, and respiratory distress.

Hypotension and Shock

Hypotension is not defined by a fixed number, but often precedes or is the manifestation of shock. Classically shock has been divided into four categories: hypovolemic, obstructive, cardiogenic, and distributive.²⁹ Hypovolemic shock is explained by hemorrhage or fluid losses. Obstructive shock indicates a structural impediment to the circulatory apparatus as seen with pericardial tamponade, tension pneumothorax, or pulmonary embolism. Cardiogenic shock occurs secondary to valvular dysfunction, arrhythmia, or ventricular compromise. Distributive shock is often a marker of an inflammatory process disrupting the integrity of small vessels that can be seen in sepsis or anaphylaxis. The classification may be overly simplistic as septic patients in distributive shock may also present with relative hypovolemia and cardiomyopathy contributing to their shock state. Still, the classification provides a useful framework through which to approach a difficult problem.

Shock is the clinical diagnosis that represents the imbalance between oxygen delivery and demand. Physiologically it is based on the principle of oxygen delivery to end organs, accomplished by adequate circulating blood volume and red blood cells, vascular tone, and cardiac function. These physiologic principles are the backbone for the early goal-directed therapy in the treatment of severe sepsis and septic shock.³⁰ Clinical signs of end-organ damage such as decreased urine output and encephalopathy as well as biomarkers (increased lactate, creatinine, troponins, and liver enzymes) are indicative of hypoperfusion and shock.

Altered Mental Status and Neurologic Deterioration

Altered mental status is a broad term encompassing a spectrum of alterations of an individual's normal mental facilities. The differential diagnosis of altered mental status can be more succinctly divided into four categories: primary intracranial processes, systemic or metabolic diseases secondarily affecting the central nervous system, exogenous toxins, and drug withdrawal.³¹ Differential diagnosis may

be difficult upon initial evaluation. Focal neurologic symptoms often indicate an intracranial process such as a stroke or seizure. Encephalopathy and delirium are more often associated with systemic illness, toxins, and withdrawal. Furthermore, toxidromes have been described with specific drug exposures and poisonings.

Deterioration in mental status can be measured serially with the Glasgow Coma Scale (GCS). A GCS of 8 or less is associated with the inability to protect one's airway and the risk of aspiration, prompting emergent transfer to a monitored setting, or intubation.³²

Respiratory Distress and Failure

Acute respiratory failure and the need for mechanical ventilation are among the most common causes of ICU admission. The cause for respiratory failure can be of a primary pulmonary pathology or secondary to cardiac, infectious, metabolic, neurologic, and overall systemic illness. An increased work of breathing, low oxygen saturation, or depressed respiratory status should all prompt an ICU evaluation as such patients rapidly deteriorate into cardiopulmonary collapse. Pulse oximetry and blood gases are readily available and can be repeated serially to determine the degree of oxygenation and ventilation deficit. When appropriate, the need for mechanical ventilation should not be delayed. In select cases, such as exacerbation of heart failure or obstructive pulmonary disease, a trial of noninvasive positive pressure ventilation (NIPPV) while implementing targeted therapies has been shown to be effective and may alleviate the need for mechanical ventilation.³³

APPROACH TO THE PRE-ICU PATIENT

Implementation of RRT is meant for the early identification of pre-ICU syndromes and prevention of cardiac arrests. While the causes for shock, neurologic deterioration, or respiratory failure may not be initially evident, the “Hs and Ts” (Table 6–1), described in Advanced Cardiac Life Support guidelines, provide a framework for diagnostics and treatment.³⁵ They are major contributing factors to developing cardiac arrest that can be identified and

TABLE 6–1 The “Hs and Ts” of advanced cardiac life support guideline.

Hs	Ts
Hypoxia	Toxins—drug overdose
Hypovolemia	Tamponade
Hypoglycemia and other metabolic disorders	Tension pneumothorax
Hypothermia	Thrombosis—coronary
Hydrogen ion—acidosis	Thrombosis—pulmonary
Hypokalemia and hyperkalemia	Trauma

potentially treated at the bedside, before transfer to the ICU. The rapid identification of these factors helps guide therapy in the crucial moments leading up to a cardiac arrest. These findings are present, or are the presenting symptoms, in many patients requiring ICU-level care.

First steps when evaluating the critically ill patient include cardiac monitoring, vital signs, pulse oximetry, and establishing intravenous access. The advanced cardiac life support and advanced trauma life support algorithms have popularized an “ABCD” approach to critically ill patients: airway, breathing, circulation, and neurological disability and differential diagnosis (Table 6–2).³⁴ A rapid primary survey evaluating for and intervening upon life-threatening conditions is a fundamental underpinning of effective resuscitation and is a useful model to follow in critical care. Clinically experienced physicians will proceed in an order dictated by their experience—often delegating tasks to team members. For the less experienced physician the framework is a reminder of the critical elements that must be assessed and intervened upon with immediacy.

Equipment and Medications

Equipment and medications are limited on general wards. When responding to a rapid response, the appropriate equipment should be brought to the bedside. The following are examples of equipment and medications that supplement standard intubation supplies and cardiac arrest medications required for the ACLS algorithm.

TABLE 6–2 An example of the ABCD approach to the pre-ICU Patient.

	Clinical Examination	Analysis	Imaging	Initial Rapid Response Interventions
Airway/ Breathing	Respiratory rate Accessory muscle use Airway patency Auscultation	Pulse oximetry Arterial blood gas Electrocardiogram	Thoracic and pleural ultrasound Vascular ultrasound Chest radiography	Jaw thrust Removal of foreign bodies Supplemental oxygen Bag valve mask ventilation Noninvasive positive pressure ventilation Intubation and mechanical ventilation Thrombolytics (myocardial infarction, pulmonary embolism) Relief of pneumothorax or plural ef usion
Circulation	Blood pressure Pulse rate and quality Capillary refill Urine output Extremity temperature Pulses: faint or bounding Auscultation	Arterial blood gas Lactate Creatinine Troponin Liver function tests Central and mixed venous oxygenation Electrocardiogram	Echocardiography Abdominal ultrasound Thoracic and pleural ultrasound Vascular ultrasound	Vascular access (peripheral, central, intraosseous) Volume administration Vasopressors Inotropes Thrombolytics (myocardial infarction, pulmonary embolism) Relief of pneumothorax or pericardial ef usion
Neurologic Disability	Neurologic Examination Glasgow Coma Scale Respiratory rate and patterns Toxidromes	Glucose Ammonia level Arterial blood gas	Brain computed tomography Brain magnetic resonance imaging Electroencephalogram	Antiepileptics and benzodiazepines (seizures) Naloxone (opiate overdose) Glucose (hypoglycemia) Supplemental oxygen (hypoxemia) Mechanical ventilation (hypercarbia) Thrombolytics (ischemic stroke)

- Airway/equipment bag: The contents of the bag should include equipment for intubation of the difficult airway. This includes laryngeal mask airways, a bougie or endotracheal tube introducer, video laryngoscopes, peep valves, and a cricothyroidotomy kit. The addition of an intraosseous infusion kit allows for rapid circulatory access when appropriate intravenous access is lacking.
- Medication bag: The contents of the bag should include medications for appropriate induction of anesthesia prior to intubation and blood pressure support. This includes propofol, etomidate, short-acting paralytics and vasoactive medications such as phenylephrine or norepinephrine.

- Portable ultrasound: Goal-directed ultrasonography during a rapid response assists in formulating a diagnosis, focusing therapy, and guiding procedures without having to transport critically ill patients to imaging suites.

The medications and equipment listed above are used as an example. Local hospital practice, protocols, equipment availability, and expertise should dictate the contents of RRT equipment.

Postoperative, Postprocedure, and Specialized Care

Often admissions to the ICU are not related to the above-described, unexpected, syndromes. Rather, they are admissions that require postoperative,

postprocedural, or specialized care. These are planned or protocolized admissions that are based on local hospital policy and procedure and the need for additional monitoring. Specialized units include, but are not limited to, surgical, cardiothoracic, neurologic, neurosurgical, burn, trauma, respiratory, and cardiac units. Unplanned, or unexpected, post-operative or postprocedural admissions are often related to the previously described syndromes.

SUMMARY

The majority of ICU admissions can be characterized by the presence of respiratory failure, a shock state, neurologic deterioration, or a combination of the three. While often times the need for ICU care is evident on initial presentation to the hospital, it is not always possible to predict the need. Pre-ICU syndromes develop rapidly, unexpectedly, and have the potential for detrimental outcomes. It is imperative to have functional rapid response systems, in terms of both triggering and response, to expedite care to such patients in a ward setting.

Biomarkers in Decision Making

Anthony Manasia, MD and Jon Narimasu, MD

KEY POINTS

- 1 An ideal biomarker has a high sensitivity and allows for clinical applications in the diagnosis, staging, prognosis, and treatment of disease.
- 2 Early identification of ischemia after the rupture or erosion of an atherosclerotic coronary plaque and before myonecrosis occurs is currently under investigation. Biomarkers of myocardial ischemia include choline, a chemical released during membrane damage; unbound free fatty acids, a chemical released by ischemic myocytes and ischemia-modified albumin.
- 3 The cardiac biomarkers B-type natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) are elevated in 80% of patients who present to the emergency department (ED) with chronic heart failure (CHF).
- 4 Neutrophil gelatinase-associated lipocalin (NGAL) is a novel serum biomarker that can identify acute kidney injury (AKI) early after the initial renal insult and can be reliably measured in the plasma by point-of-care immunoassay. NGAL levels were elevated up to 48 hours prior to the diagnosis of AKI based on the risk or renal dysfunction, injury to the kidney, failure of kidney function, loss of kidney function, and end-stage kidney disease (RIFLE) criteria in a recent study.
- 5 The use of procalcitonin (PCT) in the diagnosis and discrimination of bacterial infection, sepsis, and response to antibiotic therapy from noninfectious causes of systemic inflammatory response syndrome (SIRS) (ie, pancreatitis) is currently in use by some institutions.

INTRODUCTION

A biological marker (biomarker) is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.¹ An ideal biomarker enables sensitivity and allows for clinical applications in the diagnosis, staging, prognosis, and treatment of disease. The utility of biomarkers in clinical decision making can be

organized into a multitude of categories ([Figure 7–1](#)). Diagnostic biomarkers may afford rapid screening and stratification of patients into specific groups that may respond to a particular intervention or treatment. Prognostic biomarkers may predict the course or trajectory of disease allowing for early determination of disposition (ie, floor vs ICU) and goals of care. Surrogate biomarkers are those, which are substituted for a clinical end point (ie, response to therapy).

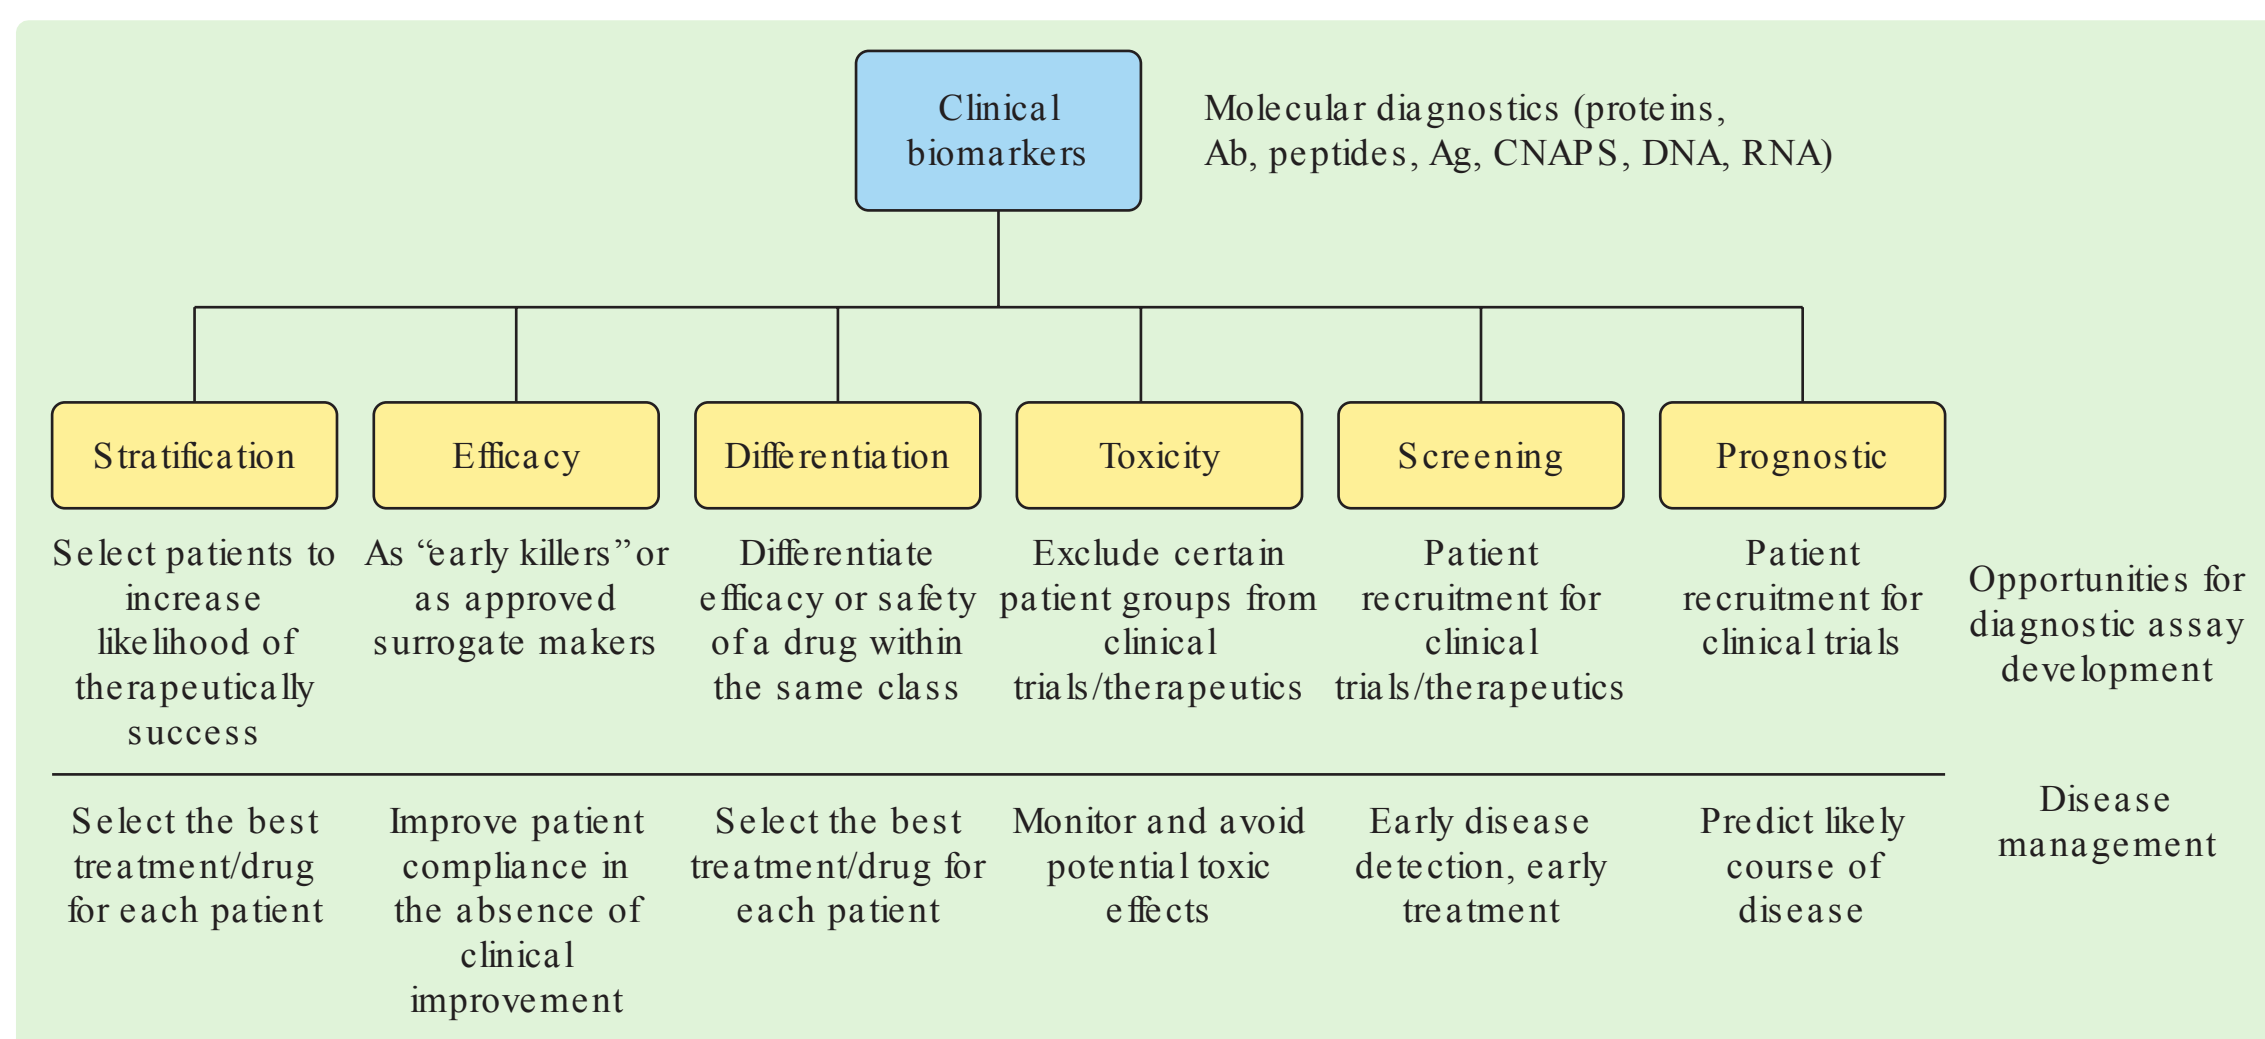

FIGURE 7–1 Clinical biomarkers: categories/types.

Currently, only a handful of serum biomarkers are used in clinical practice. This chapter will highlight these biomarkers, and provide a systematic review by organ. (Reproduced with permission from Drucker E, Krapfenbauer K Pitfalls and limitations in translation from biomarker discovery to clinical utility in predictive and personalised medicine, EPMAJ. 2013 Feb 25;4(1):7.)

CARDIAC MARKERS

Myocardial Injury

Since 1900 (with exception of 1918), cardiovascular disease has been the leading cause of mortality in the United States.² In 2009, statistics indicated that cardiovascular disease accounted for approximately 800,000 or 32% of deaths annually. Coronary heart disease also remains the number one cause of morbidity in the United States, accounting for an estimated 7.6 million myocardial infarctions (MIs), 7.8 million cases of angina pectoris, and 5.1 million occurrences of heart failure. Due to the tremendous health and economic burdens of cardiovascular disease, the search for diagnostic, prognostic, and therapeutic cardiac biomarkers continues.

Early identification of ischemia after the rupture or erosion of an atherosclerotic coronary plaque and before myonecrosis occurs is an appealing concept.³ Biomarkers of myocardial ischemia include choline, a chemical released during membrane damage; unbound free fatty acids, a chemical released by ischemic myocytes; and ischemia-modified albumin, a form of albumin that is unable to bind cobalt during myocardial ischemia. While the identification of these novel biomarkers initially showed promise, they have not been validated in clinical studies.

The World Health Organization, American College of Cardiology and European Society of Cardiology consider cardiac troponins (cTn), biomarkers of myocardial injury, as the “gold standard” for the diagnosis of MI. cTn are cardiospecific and released as an intact molecule from injured myocytes. Further specification of cTn T or I (cTnT or cTnI, respectively) is analogous to the discovery and utility of creatinine kinase myocardial band (CK-MB) after CK was identified.

In clinical use, cTn levels stratify risk in patients presenting with angina and in the determination of acute coronary syndrome (ACS). In patients with electrocardiogram (ECG) changes consistent with ST-segment elevation myocardial infarction (STEMI), the presence of cTn is primarily used to confirm the diagnosis. However, biomarker confirmation with cTn should not delay early intervention to reestablish coronary blood flow via primary percutaneous coronary intervention or thrombolysis. In addition, there is also some evidence that the level of cTn may quantify the degree and extent of myocyte injury and perhaps predict impairment of the ejection fraction.

In patients who present with angina, but without classic ST-segment elevation, cTn levels indicate those at low risk for ACS and those with

non-ST-segment elevation myocardial infarction (NSTEMI). Patients with normal cTn levels have low risk for ACS, and can undergo observation and potentially outpatient evaluation with cardiac stress testing or a myocardial perfusion scan. In contrast, patients with NSTEMI should be admitted to the hospital and should receive antiplatelet and antithrombotic therapy with or without percutaneous coronary intervention.

Although cTn remains the gold standard to determine myocardial infarction, both ischemic and nonischemic conditions can cause elevated levels. It is important to recognize these secondary causes (Table 7–1). Prognostic application of cTn in medical intensive care unit (ICU) patients has also been studied retrospectively to identify short-term and long-term survival. Elevated cTn levels were independently associated with mortality at 1-month, 1 year, 2 years, and 3 years.⁴

Heart Failure

Heart failure affects 5.1 million Americans each year, but identifying cardiac dysfunction remains a challenge in the acute care setting. Acute dyspnea caused by cardiac dysfunction (ie, heart failure) needs to be discriminated from pulmonary disease (ie, pneumonia, chronic obstructive pulmonary disease [COPD] exacerbation, acute respiratory distress syndrome [ARDS]) because management and therapeutic strategies differ. The cardiac biomarkers BNP and NT-proBNP were found to be elevated in up to 80% of patients who present to the ED with CHF.⁵

BNP is a hormone secreted by ventricular myocytes in response to increased ventricular volume and pressure, which results in wall stretch. BNP is actually a cleaved byproduct of proBNP, which is a prohormone that is upregulated within the cardiac myocyte after stimulus. As proBNP traverses the cardiac myocyte membrane into the plasma, it is cleaved into two products: BNP (active; $T_{1/2}$ 20 minutes) and NT-proBNP (inactive; $T_{1/2}$ 1.5–2 hours). The physiologic actions of BNP results in diuresis, natriuresis, vasodilation (causing decreased systemic vascular resistance and preload), anti-inflammatory, antiplatelet, and antihypertrophic effects.⁶

Diagnostic cutoff values for patients without renal failure provide the best sensitivity and specificity for BNP and NT-proBNP, and should be stratified

into ranges instead of a single value. Levels of BNP less than 100 ng/L make the diagnosis of heart failure unlikely, and a level greater than 500 ng/L favors the diagnosis.⁵ For NT-proBNP, the proposed diagnostic cutoff levels are affected by age. NT-proBNP less than 300 ng/L make the diagnosis of heart failure unlikely, and levels greater than 450 ng/L (age < 50), greater than 900 ng/L (50–75 years), and greater than 1800 ng/L (> 75 years) favor a heart failure diagnosis. Although NT-proBNP is the inactive portion of the proBNP hormone, it has a longer half-life relative to BNP, which could offer better diagnostic sensitivity. Measurements that fall in between the proposed cutoff values for BNP and NT-proBNP require additional information obtained from echocardiography for diagnosis of heart failure.

Patients with renal failure and obesity warrant special consideration because their cutoff levels for BNP and NT-proBNP are different. Further, morbidly obese patients (body mass index [BMI] > 35 kg/m²) will have a cutoff level of BNP less than 55 ng/L to rule out heart failure. For patients with stage 3 chronic kidney disease (glomerular filtration rate [GFR] 30–59 mL/min/1.073 m²), the cutoff levels that likely rule out heart failure are BNP less than 200 to 225 ng/L, and NT-proBNP less than 1200 ng/L.

In ICU patients, the role of cardiac biomarkers is limited by multisystem organ pathology. In critically ill patients, without renal disease who develop acute dyspnea, a cutoff level for BNP less than 250 ng/L may favor the diagnosis of ARDS over cardiogenic pulmonary edema.

RENAL

Acute Kidney Injury

AKI is one of the most common diagnoses encountered in acute care in the United States. It affects more than 20% of hospitalized patients,⁷ and more than 30% of critically ill patients.⁸ The development of AKI is independently associated with increased mortality. In noncritically ill hospitalized patients, the presence of AKI was associated with an overall mortality rate of 10% compared to 1.5% in patients without AKI. The mortality rate increases with the severity of AKI. In critically ill patients, mortality rates are based on the severity of AKI: stage I AKI

TABLE 7–1 Secondary ischemic and non-ischemic causes of cardiac injury.

Primary ischemic cardiac injury (PICI)		
Thrombotic coronary artery occlusion due to platelets/fibrin	ST elevation MI	
	Non-ST elevation ML(non Q wave MI plus cTn plus cTn-positive unstable angina)	
Secondary ischemic cardiac injury (SICI)		
Coronary intervention	Primary PTCA	Distal embolization from atheroma or debris Side branch occlusion
	Elective PTCA	Distal embolization or debris Side branch occlusion
Sympathomimetics	CABG	Global ischemia form inadequate perfusion, myocardial cell production of anoxia
	Cocaine abuse Catecholamine storm	Head injury, stroke, intracerebral bleeding
Pulmonary embolus Coronary artery spasm Coronary artery embolization	Presumed right heart strain or hypoxia In Japan—up to 10% of admissions for chest pain Clot Air CABG	
Coronary artery inflammation with microvascular occlusion	Vasculitidies	
	Connective tissue damage (eg, Pompe’s disease) Systemic lupus erythematosus (SLE)	
End-stage renal failure Rhythm disorders Acute heart failure Direct coronary trauma Extreme endurance exercise	More severe coronary artery disease, but 50% ESRD patients have normal coronaries Prolonged tachycardia or bradycardia with IHD Only if due to IHD	
	Extreme marathons Extreme training	Wall motion abnormalities cTn positive deaths presumed due to extreme oxygen debt producing ischemia
Non-ischemic cardiac injury (NICI)		
Known causes of myocarditis	Infection	Bacterial or viral Rheumatic myocarditis Septic shock Acute pericarditis
	Inflammation	
	Autoimmune	Polymyositis Scleroderma Sarcoidosis
	Drug-induced	Alcohol Cocaine abuse Chemotherapy
Cardiac Trauma	Toxins	Snake, puf er fish envenomation
	Direct	Motor Vehicle Accident (MVA) Stabbing
Metabolic/toxic	Cardiac surgery	
	Renal failure Multiple organ failure (MOF)	

Reproduced with permission from Collinson PO, Gaze DC. Biomarkers of cardiovascular damage and dysfunction- an overview, Heart Lung Circ. 2007;16 Suppl 3:S71-S82.

is associated with a mortality rate of 13.9%; stage II AKI of 16.4%; and stage III AKI of 33.8%.⁹

The current diagnostic criteria used to define AKI are based primarily on increases in serum creatinine (SCr) levels relative to baseline, with high associated morbidity and mortality. The search for novel serum biomarkers identifying AKI earlier after the initial renal insult, has led to the recognition of neutrophil gelatinase-associated lipocalin (NGAL). NGAL is a protein that is transcribed early in the process of renal injury, and can be reliably measured in the plasma by point-of-care immunoassay.¹⁰ In a prospective, observational study of 301 patients, investigators evaluated the utility of NGAL as an early serum biomarker of AKI compared to the commonly used RIFLE criteria.¹⁰ The RIFLE criterion, which utilizes SCr and GFR, was defined by the Acute Dialysis Quality Initiative (ADQI) group in 2004.¹¹ Results demonstrated that NGAL levels were elevated up to 48 hours prior to the diagnosis of AKI based on the RIFLE criteria (Figure 7–2). Plasma NGAL levels greater than 150 ng/mL were associated with an increased incidence of AKI of 11.8 (95% confidence interval [CI], 3.5–39.2). In addition, NGAL levels greater than 150 ng/mL were also a good predictor of renal replacement therapy. Further evaluation is required to determine if

plasma NGAL will ultimately translate into the renal “troponin” in clinical practice.

While NGAL has been demonstrated as a renal biomarker, there are others under investigation including kidney injury molecule 1 (KIM-1), cystatin-C, interleukin (IL)-6, IL-18, urinary N-acetyl-beta-(D) glucosaminidase activity (NAG), and matrix metalloproteinase 9 (MMP-9).¹⁰

Infectious Disease

Sepsis and Shock

In the United States, sepsis-related health care costs remain the number one economic burden accounting for more than \$20 billion as of 2011.¹² Even more alarming are the number of reported cases (>1,000,000), and the incidence of hospital admissions due to sepsis continues to rise each year from 266,895 in 2005 to 353,516 in 2011.¹³ However, mortality rates related to sepsis remain high (25%–50%), and account for greater than 200,000 deaths each year.¹⁴

Studies have evaluated numerous biomarkers involved in the sepsis cascade as potential targets for therapy. Unfortunately, immunotherapy trials (ie, recombinant activated protein C, eritoran tetrasodium—E5564, a toll-like receptor 4 antagonist, and talactoferrin alpha) have failed to demonstrate mortality benefit.¹⁵ Focus may need to be

FIGURE 7–2 Mean plasma NGAL concentrations at various timepoints in patients with acute kidney injury. (Reproduced with permission from Cruz DN, de Cal M, Garzotto F, et al. Plasma neutrophil gelatinase-associated lipocalin is an early biomarker for acute kidney injury in an adult ICU population, *Intensive Care Med*. 2010 Mar;36(3):444–451.)

on when to target each biomarker with immunotherapy, instead of just inhibiting or augmenting an ongoing process in the sepsis cascade. In a study of patients with severe sepsis and septic shock, levels of serum biomarkers (ie, IL-1 beta, 1ra, 6, 8, and 10; intercellular adhesion molecule, tumor necrosis factor alpha, caspase 3, d-dimer, high-mobility group protein 1, vascular endothelial growth factor, matrix metalloproteinase, and myeloperoxidase) known to be involved in the pathogenesis of sepsis were measured at various times (0, 3, 6, 12, 24, 48, 60, and 72 hours).¹⁵ The results demonstrated various times to peak levels of each biomarker ranging from 3 to 48 hours, and different patterns (ie, bimodal) of peak and nadir levels. These results indicate a 3-hour window for appropriate intervention from peak levels of some of the above biomarkers and development of sepsis. In contrast, for other biomarkers, successful immunotherapy may require multiple time-sensitive interventions based on changing levels. Further understanding of biomarkers and sepsis will lead to a new paradigm of early and “time-sensitive” goal-directed therapies.

During shock, anaerobic glycolysis produces lactate, which is converted to glucose via the Cori cycle in the liver as a source of energy. Approximately 1300 to 1500 mmol of lactate is produced each day under normal physiologic conditions by various organs including the brain, skeletal muscle, intestine, skin, and red blood cells.¹⁶ Normal serum lactate levels are less than 2 mmol/L.

Hyperlactatemia (> 2 mmol/L) is caused by excess production (ie, anaerobic glycolysis), reduced clearance, or a combination of both states. Hyperlactatemia occurs in patients with tissue dysoxia, or in other conditions where hypoxia is not the primary etiology such as SIRS and sepsis. Lactate clearance (ie, decrease of 10% from baseline levels within 2 hours and up to 12 hours), or normalization of lactate levels within 24 hours is associated with decreased mortality, organ failure, and ICU days.¹⁶⁻¹⁸

Lactate Clearance

A randomized, multicenter trial evaluated the mortality outcomes of a protocol-driven treatment plan, comparing the use of the ScvO₂ greater than 70% versus lactate clearance of 10% within 2 hours of initiating resuscitation.¹⁹ Patients with severe sepsis or septic shock were treated with a protocol consistent

with the SSC guidelines. The two treatment groups utilized resuscitation to sequentially achieve a central venous pressure (CVP) greater than or equal to 8 mm Hg, then a mean arterial pressure greater than or equal to 65 mm Hg, followed by either an ScvO₂ greater than 70% or lactate clearance greater than 10% (within 2 hours of initiating the protocol). The mortality rate in the ScvO₂ group was 23%, versus 17% in the lactate clearance group, demonstrating a mortality benefit of 6% when using lactate clearance as a primary goal of initial resuscitation.

Other studies have also supported the concept of lactate normalization, as it is known that hyperlactatemia is independently associated with increased morbidity and mortality regardless of the etiology.^{16,20}

Procalcitonin: Diagnosis of Bacterial Infections/Sepsis & Guidance of Antibiotic Therapy

Discrimination of sepsis (defined as probable or documented infection) from noninfectious causes of SIRS remains a challenge. The difficulty in diagnosing bacterial infection is a reflection of the nonspecific symptoms and signs of SIRS. Studies have revealed promise with the use of procalcitonin in the diagnosis of bacterial infection, sepsis, and response to antibiotic therapy.²¹ However, there is no single biomarker of sepsis that has 100% sensitivity or specificity.

PCT is a prohormone of calcitonin, which is synthesized in the parafollicular C cells of the thyroid gland.²² In response to inflammatory and noninflammatory mediators released by bacterial infection, procalcitonin is upregulated and produced by C cells of the thyroid and other organs (ie, liver, lung, small intestine, kidney) throughout the body. Upregulation and plasma levels increase within 6 to 12 hours of bacterial infection. PCT is specific for bacterial infection since interferon gamma is released in response to viral infection and inhibits the upregulation of PCT. Once appropriate antibiotic therapy has been administered, the levels of endotoxin and cytokines fall resulting in the decline of serum PCT levels by 50% each day. PCT has a plasma half-life of 25 to 30 hours. Plasma PCT levels correlate with the severity of infection, prognosis, allow for monitoring response to antibiotic therapy, and guide duration of treatment. The implementation of algorithms

using PCT in clinical practice have been studied and validated. Different patient populations and care settings have led to the development of practical algorithms (see Figure 7–1) with specific cutoff values of PCT.^{21,23} In low-acuity (ie, outpatient) and moderate acuity (ie, emergency department and inpatient) settings, antibiotic therapy is encouraged if the PCT level is greater than or equal to 0.25 µg/L, and strongly encouraged if the level is greater than or equal to 0.5 µg/L. In high-acuity settings (ie, ICU) or with septic patients, PCT levels should not be used to determine when to initiate antibiotic therapy but rather to guide early discontinuation of treatment.

PULMONARY

Chronic Obstructive Pulmonary Disease and Asthma

Severe exacerbations of COPD and asthma account for a significant number of hospitalizations, but the decision for ICU admission is based on clinical presentation and empiric therapy. Biomarkers evaluated include interleukins, interferons, and leukotrienes; tumor necrosis factor alpha; myeloperoxidase; eosinophil cationic protein; eosinophil peroxidase; and exhaled nitric oxide.²⁴ Unfortunately, biomarkers in COPD and asthma lack sensitivity, specificity, and have not translated into clinical medicine.

Pulmonary Embolism

The development and widespread application of computed tomography pulmonary angiography (CTPA) to diagnosis pulmonary embolism (PE) has led to a significant rise in the incidence of reported cases from 62 to 112 per 100,000.²⁵ The downside of the high-sensitivity of CTPA has led to increased diagnosis of chronic and clinically insignificant cases of PE. Mortality rates have remained steady around 12%, but complications related to the treatment of PE with thrombolysis and anticoagulation increased from 3 to 5 cases per 100,000. The challenge in the management of PE is to stratify patients into risk categories to determine which patients will benefit the most from treatment. The highest mortality (25%-50%) is associated with patients who develop hemodynamic instability and right ventricular dysfunction.²⁶ Biomarkers have been evaluated alone,

and compared to conventional scoring systems (ie, pulmonary embolism severity index [PESI]) and imaging (CTPA and echocardiography) to identify high-risk patients. proBNP greater than 600 pg/mL and BNP greater than 75 pg/mL are associated with right ventricular dysfunction and increased mortality (> 6-fold). In addition, acute right ventricular pressure overload may lead to myocardial injury and elevated cTn levels. cTnI greater than 0.1 ng/mL and cTnT greater than 0.01 ng/mL have been associated with increased mortality (> 5-fold).

d-Dimers

Fibrin degradation products (FDPs) are released when fibrin is cleaved by plasmin. d-Dimer is one of the major FDPs. d-Dimer is generated from cross-linked fibrin and an increase in d-dimer is an indication of intravascular coagulation. d-Dimer levels are helpful but not sufficient on their own to diagnose PE. However, patients with a low clinical suspicion of PE and normal d-dimer level, less than 500 ng/mL, PE can be excluded and no further testing is warranted.²⁷ In patients with a low clinical suspicion of PE, elevated levels of d-dimer (> 500 ng/mL) should prompt further testing with computed tomography (CT) angiogram. Patients with a moderate or high suspected PE should undergo imaging studies without the need of d-dimer testing. d-Dimer is best tested using quantitative and semiquantitative enzyme-linked immunosorbent assay (ELISA).

GASTROINTESTINAL

Acute Mesenteric Ischemia

Acute mesenteric ischemia is a surgical emergency with a 50% mortality rate.²⁸ Early diagnosis remains a challenge with clinicians relying heavily on a patient's clinical history, nonspecific symptoms and signs on physical examination, and laboratory studies (ie, leukocytosis, amylase, lipase, lactate) for diagnosis. CT angiography has increased the diagnostic sensitivity and specificity, but not enough to change overall mortality. Serum lactate has been used as a primary biomarker in the diagnosis of acute mesenteric ischemia, and studies have demonstrated that levels vary even in severe cases with complete arterial occlusion.²⁹

In an attempt to improve diagnostic utility, investigators have evaluated two stereoisomers of lactate: l-lactate and d-lactate. l-Lactate is produced by anaerobic glycolysis by many cells in the body and is metabolized by the liver. d-Lactate is a specific byproduct of bacterial metabolism in the lumen of the intestine that is absorbed into the bloodstream. During periods of intestinal hypoperfusion, it was proposed that bacterial overgrowth would lead to increased production of d-lactate, absorption, and plasma levels. Most laboratories measure both stereoisomers of lactate but do not distinguish between the two forms. However, when d-lactate and l-lactate were measured individually, there was no diagnostic sensitivity or specificity for acute mesenteric ischemia. Currently, studies are evaluating intestinal fatty acid-binding protein (i-FABP), which is released into the blood by injured enterocytes. Future research is needed to determine the significance of i-FABP as a biomarker in the diagnosis of acute mesenteric ischemia.

Acute Pancreatitis

Acute pancreatitis regardless of the etiology leads to a prolonged clinical course in 20% of patients, which can be complicated by multisystem organ failure and death.³⁰ Of the subset of patients who develop severe pancreatitis, the risk of death approaches 60%. In the first 2 weeks of developing acute severe pancreatitis, deaths are primarily attributed to SIRS and multiorgan dysfunction syndrome. In contrast, after 2 weeks, mortality is mostly due to sepsis-related complications.³¹ Research has focused on identifying risk factors for the development of severe acute pancreatitis. In practice, a multitude of clinical scoring systems (ie, Ranson, APACHE II, BISAP, CTSI) involving patient characteristics, radiologic findings, and biomarkers are used to predict the severity and clinical course of acute pancreatitis. Comparisons of these various scoring systems revealed that the biomarkers, IL-6, and C-reactive protein (CRP) are useful in predicting disease severity and the development of pancreatic necrosis. IL-6 is a proinflammatory cytokine released by leukocytes activated by SIRS. IL-6 and other cytokines then stimulate the production of acute-phase reactants such as CRP by the liver. For severe pancreatitis, the diagnostic timing and cutoff levels are IL-6 greater than or equal

to 50 pg/mL within 24 hours, and CRP greater than or equal to 150 mg/L at 48 hours. The use of IL-6 and CRP to identify patients at risk of developing severe, acute pancreatitis may create a window for early intervention.

NEUROLOGIC

Ischemic Stroke

Ischemic stroke affects approximately 700,000 people in the United States each year. Diagnosis is based on clinical history, physical examination, and initial imaging with computed tomography. In the last decade, there has been limited success in evaluating potential stroke biomarkers.³² The inability to identify a single reliable diagnostic biomarker for ischemic stroke is likely due to various underlying mechanisms and the blood-brain barrier. Other studies have evaluated biomarker panels (ie, matrix metalloproteinase 9, BNP, d-dimer, S-100 β) but clinical utility has not been demonstrated.

Traumatic Brain Injury

In the United States, traumatic brain injury (TBI) affects 1.7 million people and accounts for approximately 50,000 deaths.³³ Diagnosis of TBI is based on clinical findings and reliance on imaging with CT and magnetic resonance imaging (MRI). Imaging modalities have limitations with regard to time sensitivity, ability to predict the evolution or extent of injury, and detection of intracranial hypertension, all of which may ultimately delay surgical intervention. Ideally, brain biomarkers would help clinicians triage patients with TBI through the early diagnosis of diffuse and focal injury, and intracranial hypertension. Research has evaluated numerous brain biomarkers, which are mainly proteins released into the bloodstream after TBI. Some of the brain biomarkers which have been studied include neurofilament, tau protein, microtubule-associated protein 2, myelin basic protein, neuron-specific enolase, S-100 β , glial fibrillary acidic protein, ubiquitin c-terminal hydrolase-L1, alpha-II spectrin breakdown product, and microRNA. Unfortunately, the diagnosis of TBI and intracranial hypertension utilizing brain biomarkers is in the early phase of discovery.

CONCLUSION

The use of biomarkers in current clinical practice is limited. However, with the exponential growth in biomarker research, there is enthusiasm that our expanding knowledge will translate into improved decision making and outcomes. Continuous evaluation of our practice and incorporation of these new ideas and studies has the potential to improve patient care. The future development and adoption of guidelines and protocols using biomarkers has potential to minimize variability and maximize benefit. Through thoughtful study design and collaboration, the biomarker era will surely transform and shape the future of medicine.

Controversies in Therapeutic Hypothermia

Jose R. Yunen, MD and Rafael Tolentino, MD

Induced TH is currently used in several medical conditions. However, it is by far more commonly employed in today's clinical practice to prevent or diminish hypoxic-ischemic encephalopathy (HIE) and its deleterious outcomes in postcardiac arrest patients.

OVERVIEW OF HIE

HIE is a syndrome of acute global brain injury resulting from critical reduction or loss of blood flow and supply of oxygen and nutrients. Some of the terms used to describe this clinical syndrome include anoxic encephalopathy, postcardiac arrest brain injury, and other terms denoting a diminution of blood or oxygen to the whole brain. The pathologic injury to the brain results in cell injury and death from an intracellular energetic crisis that selectively affects vulnerable areas such as CA-1 of the hippocampus, caudate, putamen and neocortex, and relative sparing of brain stem. High-quality cardiopulmonary resuscitation (CPR) with prompt restoration of spontaneous circulation is crucial to survival. The mainstay of postresuscitation care is TH. ICU management also includes optimizing hemodynamic status, diagnosing and treating seizures, and other supportive care.

The most common cause of HIE is cardiac arrest, which is commonly secondary to cardiac etiologies (infarction or arrhythmia). Each year over half a million cardiac arrests occur in the United States. Approximately 380,000 of these occur outside of health care facilities, and another 210,000 occur in hospital every year.

Outcomes of Postanoxic Brain Injury After Cardiac Arrest

The outcome of patients experiencing SCA is poor. The primary cause of mortality after SCA is primarily

related to the effects of anoxic brain injury and not necessarily from cardiac complications.

Outcomes differ based on initial rhythm found at scene of SCA. For example, outcomes are poorer with so-called “nonshockable” rhythms (asystole, pulseless electrical activity [PEA]) compared to “shockable” rhythms (ventricular tachycardia [VT] or ventricular fibrillation [VF]). Improved survival may be best when initial rhythm is VF, but still dependent on prompt delivery of effective CPR. Clinical factors identified as predictors of greater likelihood of survival to hospital discharge are witnessed arrest, VT or VF as initial rhythm, return to spontaneous circulation (ROSC) during first 10 minutes, and longer duration of overall resuscitation efforts.¹

The Controversies

Since the development of modern CPR techniques in the 1950s, numerous pharmacologic trials with putative neuroprotective effects have failed to improve survival and quality of life of patients resuscitated from cardiac arrest. Mild TH has become a standard component of postcardiac arrest to prevent or mitigate various types of neurologic injury. The ultimate goal of resuscitation is to improve survival with good neurologic outcome. The evidence supporting this practice came from two randomized trials published consecutively in 2002—one small-sized Australian study done by Bernard et al that showed good neurologic outcome in 49% survivors in the hypothermia to 33°C group versus 26% of normothermic patients, among 77 patients with out-of-hospital cardiac arrest due to VT.² The other, a medium-sized randomized controlled multicenter trial was done in 9 European centers by the Hypothermia After Cardiac Arrest (HACA) group wherein among 273 patients with out-of-hospital

arrest due to shockable initial rhythms (VF or VT), hypothermia to 34°C led to improved neurologic outcome 55% versus 39% with usual care.³

TH (also called targeted temperature management) had demonstrated a robust benefit with a number needed to treat (NNT) of 6. While these 2 landmark studies focused on out-of-hospital cardiac arrest with VT/VF as initial rhythms, subsequent studies showed likely survival and quality-of-life benefits for victims of cardiac arrest with initial rhythms of asystole or PEA with hypothermia (TH).⁴ While no prospective randomized controlled trial has been undertaken to show the benefit of TH in patients with PEA and asystole,⁵⁻⁸ existing studies have also shown that TH is not harmful either. Current recommendations strongly favor cooling all comatose cardiac arrest victims regardless of presenting ECG rhythm in accordance to the International Liaison Committee on Resuscitation (ILCOR) guidelines (American Heart Association [AHA] class I recommendation for out-of-hospital arrest with VT/VF as the initial rhythm, and IIB for those with PEA and asystole as initial rhythm), and the European Resuscitation Council.⁹

This approach was recommended despite arguments by some investigators that the evidence was weak, owing to the risk of bias and small samples.^{10,11} Furthermore, its use has been extended to cardiac arrest of other causes and with other presenting rhythms as well as to the in-hospital setting.¹² Although a Cochrane review supports these guidelines,¹³ some investigators have suggested a need for additional trials to confirm or refute the current treatment strategy.¹⁴⁻¹⁶ In addition, one trial showed that fever developed in many patients in the standard treatment group.¹⁷ It is therefore unclear whether the reported treatment effect was due to hypothermia or to the prevention of fever, which is associated with a poor outcome.¹⁸⁻²⁰

The subsequent debate has focused on 2 issues. The first issue is whether TH should be extended to patients outside the originally described populations.²¹⁻²³ It may be reasoned that the potential benefits of temperature management on brain injury due to circulatory arrest would be the same irrespective of the cause of arrest. However, whole body hypothermia influences all organ systems and any potential benefit should be balanced against

possible side effects.²⁴ The population of patients with cardiac arrest is heterogeneous, and the potential risks and benefits of temperature intervention may not be the same across subgroups. The second issue is the most beneficial target temperature for therapeutic hypothermia.²⁵ The recommended temperature of 32°C to 34°C has been extrapolated from experiments in animals^{26,27}; however, similar results have been observed with milder cooling.²⁸

AREAS OF UNCERTAINTY

Therapeutic Hypothermia in Nonshockable Cardiac Arrest

There are less robust recommendations with the use of mild TH in cardiac arrest with nonshockable initial rhythm (PEA or asystole). Only few studies have been published to evaluate the potential benefit of therapeutic hypothermia in comatose subjects presenting with nonshockable initial rhythm with conflicting results. The meta-analysis of studies by Kim et al done before 2010 using mild therapeutic hypothermia in survivors of nonshockable cardiac arrest found that TH is associated with reduced in-hospital mortality but no significant neurologic benefit.²⁹ Three retrospective analyses of out-of-hospital nonshockable cardiac arrest found possible improvement of neurologic outcomes using TH.³⁰⁻³² A large cohort study by Dumas et al found no benefit for therapeutic hypothermia in nonshockable cardiac arrest.³³

It is not clear whether other factors influence the outcome in nonshockable cardiac arrest. It would be logical to think that neurologic injury whether shockable or nonshockable cardiac arrest could have the same mechanism. Adult patients with PEA or asystole cardiac arrest are usually sicker, with ongoing hypoxemia and circulatory shock that often result in bradycardia or hypotension before progressing to pulseless cardiac arrest.³⁴ Additional brain insult may have been incurred during prearrest asphyxia and circulatory shock.

Cooling and Rewarming

The optimal time to initiate TH, the optimal method of cooling, the optimal rate of induction, level and duration of hypothermia, and the optimal rate of

rewarming are still unknown. In animal models of cardiac arrest, the benefit of hypothermia declines when it is started more than 15 minutes after Reperfusion.³⁵ Bernard et al^{36,37} hypothesized that early initiation of cooling in the field after ROSC would improve both survival and neurologic outcome. Rapid cooling after resuscitation from cardiac arrest with an intravenous infusion of cold saline appears feasible and safe.³⁸ Infusion of cold intravenous fluid is an attractive strategy to achieve early cooling because of its portability, ease in administration, and potential widespread availability in the prehospital setting. However, no benefit was observed among 234 patients resuscitated from prehospital VF and then randomized to early field cooling.³⁹

T is large randomized trial⁴⁰ found that prehospital, rapid infusion of up to 2 L of 4°C normal saline did induce mild hypothermia faster than standard care but did not improve survival or neurologic status at discharge after resuscitation from prehospital shockable (VF) or nonshockable (without VF) cardiac arrest. The resuscitation and intervention were performed by paramedics from emergency medical service (EMS) agencies with a high overall rate of resuscitation. The intervention reduced core body temperature by hospital arrival, and patients reached the goal temperature about 1 hour sooner than in the control group. The intervention was associated with significantly increased incidence of rearrest during transport, time in the prehospital setting, pulmonary edema, and early diuretic use in the emergency department (ED). Mortality in the out-of-hospital setting or ED and hospital length of stay did not differ significantly between the treatment groups.

Clinical evidence in humans undergoing intra-arrest therapeutic hypothermia (IATH) is limited, but has been shown to be both safe and feasible, and in one study it showed improvements in ROSC, survival to hospital discharge, and neurologic outcomes.⁴¹⁻⁴³

In the pivotal clinical trials,²⁻³ therapeutic hypothermia was achieved with use of noninvasive surface cooling methods by application of ice packs in the Australian trial and with the use cold air mattress covering the entire body in the European trial. Other studies made use of invasive core cooling via intravascular catheters, ice-cold fluid infusion, peritoneal lavage, and use of extracorporeal circulation. Each

method has their advantages and disadvantages. It is important however that the chosen method could rapidly induce cooling as well as maintain the target temperature within a narrow range.

Temperature Modulation

After maintaining a TH of 32°C to 34°C for 24 hours, active, controlled rewarming at a rate of 0.25°C to 0.5°C per hour is recommended until a core temperature of 36°C to 37°C is achieved. Upon rewarming, the therapeutic temperature management system should remain in place for a further 48 to 72 hours to ensure normothermia, protecting the brain from the detrimental effects of hyperthermia. Rebound pyrexia is a common phenomenon occurring in about 40% of patients posttherapeutic hypothermia. Only temperatures greater than 38.7°C appear to be associated with worse neurologic outcomes in patients who survive to discharge.⁴⁴ The mechanism for this common presentation of fever after therapeutic hypothermia is not well understood, however several factors are thought to contribute to its presence: altered thermoregulation from damage to thalamic structures, rebound hyperthermia, infection, and proinflammatory states all are likely contributors.

Shivering

Another important consideration when treating with hypothermia is the management and prevention of shivering. Shivering is a centrally mediated thermoregulatory response that normally sets in at 35.5°C, and is usually overcome below 34°C. However, these reference temperatures apply to healthy individuals, and may not be the same in all cardiac arrest patients. The absence of shivering after induction of hypothermia, or spontaneous hypothermia prior to induction of hypothermia has been associated with worse outcomes⁴⁵; it is possible that damage to the hypothalamus impairing thermoregulation may be a marker for more severe injury. On the other hand, the presence of shivering is known to increase body temperature which has been shown to worsen brain injury and negatively impact outcome.⁴⁴

Does It Really Work?

To make things more uncertain, in the largest randomized trial yet published in 2013, Nielsen et al

probe further whether TH is effective in cardiac arrest with and without shockable rhythms, if fever is also prevented as standard of care. This study included 939 patients after out-of-hospital cardiac arrest of presumed cardiac cause between 2010 and 2013 in 36 centers in Europe and Australia, regardless of the initial rhythm (80% had a shockable initial rhythm, 12% had asystole, and 8% had PEA). They were randomized to receive targeted temperature management using any cooling method to either 33°C or a near-normal temperature of 36°C, induced as soon as possible, for 28 hours, followed by rewarming, followed by fever-reduction methods for 72 hours postarrest. This trial showed that hypothermia at a targeted temperature of 33°C did not confer a benefit as compared with a targeted temperature of 36°C regardless of initial rhythm. There were no differences between groups in the rate of death (50% with hypothermia, 48% without), or in the composite outcome of poor neurologic outcome or death after 6 months (risk ratios were almost exactly 1). When the analysis was restricted only to the 80% of subjects with shockable cardiac arrest, there was still no benefit from TH: The relative risk for death among the cooled patients was 1.06.

The investigators did not find any harm with a targeted temperature of 33°C as compared with 36°C. However, it is worth recognizing that for all outcomes, none of the point estimates were in the direction of a benefit for the 33°C group. On the basis of these results, decisions about which temperature to target after out-of-hospital cardiac arrest require careful consideration.

There are multiple possible explanations for the absence of benefit from lower temperatures in patients with cardiac arrest.⁴⁶ The population was less select than in previous trials, including patients with shockable rhythms and those with nonshockable rhythms. There has been evolution of intensive care over the past decade, and improvements in patient care may have reduced the potential incremental benefits of a single intervention. In addition, illness severity varies greatly among patients with cardiac arrest, and there may be subgroups of patients who do benefit from induced hypothermia but who were not designated in advance. Particularly if the degree or duration of hypothermia must be adjusted to

match the severity of brain injury, the benefits to a subgroup may be missed in a trial of one regimen of hypothermia for all comers.

One interpretation of these results is that they reinforce the importance of controlling temperature, even while they question whether 33°C is the best temperature. For example, many patients in the “normothermia” group of the older trials actually became hyperthermic,^{47,48} which is deleterious.^{49,50} The exceptional rates of good outcomes in both the 33°C and 36°C groups in the present trial may reflect the active prevention of hyperthermia.

Further investigation is needed to address and define the population of cardiac arrest patients for whom the costly and intensive method of therapeutic hypothermia should be applied to or withheld.

Other Applications

Hypothermia is utilized in the management of severe traumatic brain injury (TBI) to lower cerebral metabolic rate of oxygen (CMRO₂) despite the lack of unequivocal evidence supporting its use. Most single-center studies suggest that induced hypothermia is associated with improved outcome. However, 2 large randomized multicenter studies in adults with severe TBI (National Acute Brain Injury Study: Hypothermia I and II) failed to show benefit,^{51,52} and a randomized study of hypothermia in children with TBI suggested harm.⁵³ While mild-to-moderate hypothermia has not been shown to improve outcome, the preponderance of literature suggests it is effective in lowering intracranial pressure (ICP).

In laboratory investigations of traumatic spinal cord injury, no treatment appears as promising as therapeutic hypothermia. The current issue remains translating this putative success into an approved human clinical therapy. The issue began to receive copious public interest after the case of football player whose recovery was widely credited to TH. He was said to be complete (ASIA A) below the clavicles. Of note, he received methylprednisolone infusion in the ambulance as well as IV chilled saline and ice packs to the groin. In the ED, he was hemodynamically stable with a temperature of 36°C. His C3-C4 facet dislocation was operatively reduced about 3 hours after injury. The following day, he was cooled for several days at 33°C, recovering strength about 15 hours postinjury.⁵⁴ Was this the effect of

hypothermia, or of the combination of steroids and early open reduction with adjunctive hypothermia? Such is the potential confounding where steroids and other aspects of care have varied in the setting of varied hypothermia protocols. For now, the use of TH after spinal cord injury (SCI) is considered experimental.

A recently published multicenter randomized controlled clinical trial⁵⁵ by Mourvillier et al showed that moderate hypothermia did not improve outcome in patients with severe bacterial meningitis and may even be harmful. After inclusion of 98 comatose patients, the trial was stopped early at the request of the DSMB because of concerns over excess mortality in the hypothermia group (25 of 49 patients [51%]) versus the control group (15 of 49 patients [31%]; relative risk [RR], 1.99; 95% confidence interval [CI], 1.05-3.77; $P = 0.04$).

The use of therapeutic hypothermia poses some potential risks, and some considerations need to be noted for its possible adverse effects. The clinical trials showed nonsignificant occurrence of adverse events between TH and control groups. Nonetheless, the more common adverse conditions to be vigilant for include pneumonia, sepsis, bleeding, electrolyte abnormalities, cardiac arrhythmias, and dysglycemia.⁵⁶ Establishing treatment protocols of care for induction and maintenance of hypothermia and rewarming, as well as tracking and correction of potential adverse events have enhance the delivery of care and contributed to the success of the TH.

Bedside Technology

Tara T. Bellamkonda, DO; Victor Murgolo, CCRN and
John M. Oropello, MD, FACP, FCCP, FCCM

9

KEY POINTS

- 1 Physicians, advanced care practitioners, and nurses all share the responsibility of having basic knowledge about bedside technology to properly manage patients as well as to ensure patient safety and reduce complications due to user error.
- 2 Standard pulse oximeters use transmittance spectrophotometry, that is, the light source and photodetector regions of the sensor should be directly opposite each other; they are completely unreliable if placed on the forehead or in any configuration that does not allow the transmitter and receiver to be opposite each other.
- 3 Medical air is 21% oxygen from a yellow-coded outlet that is used to power air-driven medical equipment; 100% oxygen supplied by a green-coded outlet is for oxygen delivery to the patient. Make sure they are connected properly.
- 4 Patients on positive end-expiratory pressure (PEEP) to maintain oxygenation, and require bag-valve-mask (BVM) ventilation during disconnection from mechanical ventilation, should be ventilated with a BVM containing a built-in PEEP valve or with a PEEP valve added to the exhalation port of the BVM.

The critically ill patient is in constant flux and both monitoring and therapeutic equipment are essential for managing these patients in the intensive care unit (ICU). Physicians, advanced care practitioners, and nurses all share the responsibility of having basic knowledge about bedside technology to properly manage patients as well as to ensure patient safety and reduce complications due to user error.

BEDSIDE MONITORING SYSTEM

The bedside monitor is the most prominent device garnering the most attention for both medical staff and patients and their families. Bedside monitoring

is designed to display, store, and trend the patient's heart rate, respiratory rate, blood pressure reading (noninvasive and invasive), oxygen saturation, electrocardiographic (ECG) tracing, and pressure waveforms generated from arterial, venous, or bladder catheters. The individual bedside monitor is connected to a computerized central monitoring system outside of the patient's room that will sound an alarm when abnormal measurements are recorded prompting immediate notification of the ICU staff and evaluation of the patient.

Alarm limits and scales are set by the nursing staff depending on the patient's clinical status (Figure 9–1). For instance, the ECG scale may be

FIGURE 9–1 Monitor settings.

set to amplify the tracing 2- to 4-fold in a low-voltage state. Pressure waveform scales can vary based on the patient’s pressure range; generally, the right atrial pressure is set at 20 mm Hg, pulmonary artery systolic pressure is set at 40 mm Hg, and systolic arterial blood pressure is set at 180 mm Hg.¹

Electrophysiologic Monitor

Cardiac monitoring is indicated for all critically ill patients and is used for the assessment of hemodynamics, rhythm diagnosis, and detection of ischemic changes. Monitors can employ 3-lead or 5-lead wire systems to depict the electrical activity of the heart; however, 5-lead systems are most common for continuous monitoring and provide a readout of 2 or more leads simultaneously.¹

Lead placement must be standardized in order to maintain precise and accurate results and interpretation (Table 9–1). In order for the monitor’s heart rate counter to detect the correct heart rate, the height of the R wave should be twice the height of the other electrocardiographic waves. The alarm mechanism relies on R-wave height for proper detection; false alarms can occur if T-wave height is equivalent to R-wave height, which causes double counting.¹ Most monitors have the capability of taking a 12-lead ECG. In terms of lead placement, when only monitoring, the lower limb leads should be placed on the abdomen to pick up the breaths, when taking a 12-lead ECG they should be placed on the thigh.

Electrode resistance changes as the gel dries; if a problem occurs with one electrode, it is

TABLE 9–1 **Electrode placement for 5-lead system.**

Electrode	Placement
Right arm (RA)	Apply to the right shoulder near the junction of the right arm and torso
Left arm (LA)	Apply to the left shoulder near the junction of the left arm and torso
Right leg (RL)	Apply at the level of the lowest right rib, on the right abdominal region, or right hip
Left leg (LL)	Apply at the level of the lowest left rib, on the left abdominal region, or left hip
Precordial (choose either V ₁ or V ₆)	V ₁ Apply to fourth intercostal space on right sternal border V ₆ Apply to fifth intercostal space on midaxillary line

Data from AACN, Wiegand DJ: ACCN Procedure Manual for Critical Care, 6th ed. St. Louis, MO: Elsevier; 2011.

recommended that all electrodes be changed to prevent discordance in resistance between electrodes.¹ Other key elements needed to ensure proper cardiac monitoring include adequately preparing the skin by cleaning and drying the sites of lead placement, testing the center of the pregelled electrode to make sure it is not dry, and reducing tension on wires. If these measures are not performed, interference and incorrect recordings can result.

Pulse Oximetry

Hemoglobin oxygen saturation is measured by pulse oximetry and is expressed as the percentage of oxygen (O₂) that hemoglobin carries relative to the total amount of hemoglobin that is capable of carrying oxygen and is noted as “Spo₂” to differentiate it from “Sao₂” obtained from arterial blood gas analysis. Pulse oximetry employs the technologies of spectrophotometry and optical plethysmography. Spectrophotometry estimates the hemoglobin oxygen saturation by using a light source with 2 light-emitting diodes (LEDs) that emit light at red (660 nm) and infrared (940 nm) wavelengths. Deoxy-hemoglobin absorbs red light and oxyhemoglobin absorbs infrared light; absorbed light is transmitted

to a photodetector and converted to a digital value. Optical plethysmography detects pulsatile arterial changes at the pulse oximeter sensor site as the path length of light through the sensor site alternately increases or decreases with each pulsation.² The plethysmography component of the pulse oximeter differentiates light absorption by hemoglobin from light absorption by surrounding tissue.

Pulse oximeter sensor probes should be placed on the best pulsatile vascular bed available; potential sites include fingers, great toe, and earlobe. Sensor probes should not be used on sites that are near indwelling arterial catheters, blood pressure cuffs, or areas of venous engorgement such as arteriovenous fistulas and blood transfusions. Standard pulse oximeters use transmittance spectrophotometry, that is, the light source and photodetector regions of the sensor should be directly opposite each other on the vascular bed and should be positioned so that all light from the sensor makes contact with perfused tissue beds. This minimizes ambient light interference and optical shunting which occurs when light bypasses the vascular bed.¹ If these probes are placed on the forehead or nasal bridge (as is sometimes erroneously done if there is difficulty detecting an adequate pulse waveform on the digits or earlobe) or in any configuration that does not allow the transmitter and receiver to be opposite each other, the SpO_2 is completely unreliable. Specialized pulse oximeters that use reflectance spectrophotometry can be placed on the forehead and give reliable SpO_2 readings. Make sure you know the capabilities of the device used in your ICU.

Two-wavelength pulse oximetry as described above is standard, but is inaccurate in the presence of dyshemoglobins such as carboxyhemoglobin and methemoglobin. Other causes of spurious readings (usually erroneously decreased SpO_2) include low perfusion states, clinical motion, venous pulsation at sensor site, dark skin, intense ambient light, nail polish, artificial nails, and intravenously administered dyes such as methylene blue, indigo carmine, and indocyanine green.²

Transducer System

The function of the transducer system is to convert a biophysical event into an electrical signal that is

FIGURE 9–2 Multiple-pressure transducer system.

transmitted as a waveform to the bedside monitor. The transducer system can be a single-pressure unit for arterial or right atrial monitoring or a multiple-pressure unit for arterial, right atrial, and pulmonary artery monitoring (Figure 9–2). The system consists of a catheter, pressure tubing, stopcocks, and a flushing device.

To ensure accuracy, the system must be zeroed against atmospheric pressure and then leveled with the phlebostatic axis which approximates the right atrium. The phlebostatic axis is located at the intersection of an imaginary line from the fourth intercostal space at the sternal border extending laterally to the right chest and the midaxillary line with the patient in supine position with the head of the bed between 0° to 45°.

The pressure bag (Figure 9–3) should encase a bag of normal saline and be inflated to 300 mm Hg. If blood is noted to be flowing back into the system, the pressure is inadequate. Inadequate pressure may be due to an empty bag of normal saline, initially inadequate inflation of the pressure bag or later deflation of the pressure bag from leaks; or the tubing connected to the catheter might be disconnected from the circuit.

Gas Delivery Systems

Flowmeters (Figure 9–4) measure the flow rate of the gas (usually medical air or oxygen) attached to the meter. Medical air or compressed air is filtered atmospheric air (ie, 21% oxygen, yellow-coded

FIGURE 9–3 Pressure bag.

FIGURE 9–4 Flowmeters. Compressed air (color-coded yellow) on the left; oxygen (color-coded green) on the right.

outlet) and its clinical uses include nebulizer treatments, providing clean air in ventilators, and powering air-driven medical equipment. Oxygen is 100% oxygen (green-coded outlet).

Nasal cannulae deliver oxygen at flow rates of 0.5 to 6 L/min and are generally more comfortable for patients than face masks, making talking and eating easier. Although it can be approximated that the fraction of inspired oxygen (F_{iO_2}) increases by 0.03 to 0.04 per increase of 1 L/min in oxygen flow rate, this estimate is usually inaccurate as F_{iO_2} also depends on the patient's tidal volume, inspiratory flow rate, respiratory rate, and the volume of the nasopharynx.³ Nasal cannulae are effective in the setting of mouth breathing since inspiratory air flow occurs while breathing through the mouth which causes entrainment of oxygen from the nose via the posterior pharynx.³ A bubble canister (Figure 9–5) for humidification should be used when patients require more than 4 L of oxygen to minimize irritation of nasal and oropharyngeal mucosa.

A simple face mask or variable performance mask delivers oxygen at flow rates of 5 to 8 L/min with a corresponding F_{iO_2} of 0.40 and 0.60, respectively.⁴ The mask has holes on either side for entrainment of air and venting of exhaled gas but rebreathing may occur if the expiratory pause is absent. The F_{iO_2}

FIGURE 9–5 Bubble canister for delivery of humidified oxygen therapy or nebulizer treatments.

FIGURE 9-6A Venturi-style face mask.

delivered is variable according to flow rate, pattern and rate of ventilation, inspiratory flow rate, and fit of mask and should not be used in patients who require a fixed oxygen concentration.³

The air-entrainment or Venturi mask (Figure 9-6A) delivers a predetermined and fixed oxygen concentration mechanistically by the Bernoulli principle. The mask comes with color-coded concentration dials or dilator jets labeled with the corresponding oxygen flow rate required for the desired fixed delivery of oxygen concentration ranging from 24% to 60%. The differently colored dilator nozzles (Figure 9-6B) have apertures of varying

FIGURE 9-6B Color-coded concentration nozzles.

FIGURE 9-7 Non-rebreather face mask.

size that control the amount of atmospheric air entrained (a smaller nozzle entrains more room air and delivers lower F_{IO_2}) and subsequently the amount of inspired oxygen delivered to the patient. Expired gas rapidly exits the mask due to high flow rates and rebreathing does not occur.³

A non-rebreather mask (Figure 9-7) has 3 one-way valves in order to provide an inspired oxygen concentration of 100% and to allow venting of exhaled gas and prohibit entrainment of room air.⁴ However they usually deliver less than 100% (eg, ~60%-80%) F_{IO_2} due to entrainment of room air since a completely sealed face mask could result in asphyxiation. Non-rebreather masks should not be used for extended periods of time given risk of absorption atelectasis and oxygen toxicity.

The bag valve mask (BVM) (often called an Ambu bag) is a portable device that provides intermittent positive-pressure ventilation with a self-inflating bag and one-way valve (Figure 9-8). The valve has 3 distinct ports: an inspiratory inlet which permits the entry of fresh gas during inspiration, an expiratory outlet for the exit of exhaled gas, and a connection to the face mask or endotracheal tube.³

While specifications may vary according to the manufacturer, the volume of an adult-sized BVM is 2100 mL. The average stroke volume delivered with one hand is 600 mL and using two hands yields 900 mL. A reservoir bag or corrugated tube is attached to the tubing and should be fully extended to its maximum length for maximum concentration of oxygen (90%

FIGURE 9–8 Bag valve mask (Ambu bag).

for reservoir bag and 100% for corrugated tube). The recommended oxygen flow rate is 15 L/min. Patients that need PEEP to maintain oxygenation (eg, adult respiratory distress syndrome [ARDS]) and require BVM ventilation during disconnection from mechanical ventilation (eg, for transport, ventilator troubleshooting) should be ventilated with a BVM containing a built-in PEEP valve or with a PEEP valve added to the exhalation port of the BVM. This PEEP valve is adjusted to provide the current level of PEEP set on the ventilator and maintain oxygenation during BVM.

BASIC VENTILATOR SETUP

The mechanical ventilator circuit includes a conventional humidifier or disposable heat and moisture exchangers to minimize the drying effect of gases that flow from the ventilator since the natural humidification of gas that occurs in the upper airways is circumvented by endotracheal intubation.

FIGURE 9–9 Ventilator with humidifier on the left and gas tubing on the right.

The yellow tubing for compressed air and the green tubing for oxygen delivery that exit the back of the ventilator should be attached to the appropriate wall outlets (Figures 9–9 and 9–10).

WALL SUCTION REGULATION

Disposable wall suction (Figure 9–11) is most commonly used in the ICU setting and can be attached to orogastric (OG) or nasogastric (NG) tubes, abdominal sump drains, or chest drainage systems. Low intermittent suction is used for small-bore OG and NG tubes to minimize damage to the gastric mucosa. Low continuous suction is used with OG or NG Salem sump drains because they have an additional air vent which prevents the drain from adhering to the gastric mucosa due to force of suction.

The suction regulator displays the degrees of suction (low, medium, high, and full vacuum) and dials to select the degree of suction and intermittent versus continuous suction (Figure 9–12). If the

FIGURE 9–10 Compressed air (yellow) and oxygen (green) outlets from the wall (right) and entering the back of the ventilator (left).

suction is not working, disconnect from the drainage canister and feel for suction flow; make sure that caps and lids are secured tightly on the collection canister.

INFUSION DEVICES

Smart pumps are the standard of care for administering intravenous therapy in order to maximize patient safety. The device incorporates computerized dose error reduction software with a library of intravenous drugs and fluids and their administration rate limits.⁵ Patient data is first entered

FIGURE 9–11 Vacuum outlet.

FIGURE 9–12 Wall suction setup displaying the suction regulator attached to the collection canister below.

FIGURE 9-13 Smart pumps attached to a central module.

into the computer module followed by selection of the drug or fluid and its concentration and rate; if the rate selected is predetermined to be unsafe, the pump will not allow administration of the therapy. Pumps may alarm if air is detected in the tubing or if the tubing is kinked causing high pressure in the circuit. Smart pumps are capable of many infusion modalities including large-volume pump, syringe or epidural delivery, and patient-controlled analgesia (PCA) ([Figure 9-13](#)).

PCA can be ordered as a basal or continuous infusion, patient-initiated boluses only, or both an established basal rate with intermittent boluses. The PCA prescription is entered into the smart pump and should include whether the patient is opiate naive, normal, or tolerant, the concentration of medication, basal rate, loading dose, demand dose, lockout interval, and cumulative dose limit over 1 or more hours.

EXTERNAL TEMPERATURE CONTROL DEVICES

Core temperature monitoring must be continuous when using external warming or cooling devices and can be obtained from pulmonary artery, bladder, or esophageal temperature probes. The Bair Hugger is a forced-air warming blanket that can raise a patient's core temperature 2°C to 3°C an hour by delivering warm airstreams onto the patient's skin.¹

Traditional cooling or hypothermic blankets utilize a reservoir filled with distilled water that is cooled to the targeted temperature that flows to the blanket through hoses. The device can be turned off manually or automatically once the desired body temperature is reached; however, the patient's temperature probe must be connected to the cooling blanket in order for the unit to function in automatic mode.¹

SEQUENTIAL COMPRESSION DECOMPRESSION DEVICES

Sequential compression decompression devices (SCDs) are used to reduce the risk of deep venous thrombosis and consist of garments or bladders applied to the calves and a pump system ([Figure 9-14](#)). The garments come in 3 sizes—small, medium, and extra large. Foot pumps are available for patients who require a size beyond extra large.

The compression cycle entails 40 mm Hg of pressure applied for 12 seconds followed by deflation for 48 seconds. The alternate leg then undergoes a compression/decompression cycle 30 seconds after deflation is completed for the preceding leg. The skin under the bladder should be cleaned each nursing shift, as excess moisture can be associated with skin damage.

Contraindications to pneumatic compression include severe vascular disease, active wounds involving the lower extremities, conditions that could deteriorate due to augmented preload, and known or suspected (eg, after acute pulmonary embolism) deep venous thrombosis.

BED ELECTRONICS

Modern critical care beds have many capabilities including measuring patient weight, providing chest physiotherapy, promoting patient mobility, and reducing the incidence of pressure ulcers and ventilator-associated pneumonia ([Figures 9-15 through 9-17](#)).

Weights are determined after zeroing the bed and are stored in the electronic interface. The bed should be kept at the lowest height to maximize patient safety and reduce the risk of falls and can be

FIGURE 9–14 Sequential compression decompression (SCD) device. Bladder (top) and pump (bottom).

locked so that patients are unable to modify the bed position. Patients who are spontaneously breathing should be in the sitting position to optimize their respiratory status. Mechanically ventilated patients should have the head of bed elevated to 30° to enhance diaphragmatic excursion, decrease

FIGURE 9–15 Critical care bed.

FIGURE 9–16 Bed positions.

FIGURE 9–17 Bed control panel.

intrathoracic pressure, and aid in preventing aspiration and ventilator-associated pneumonia.

Continuous lateral rotation therapy causes rotation of the bed by an arc of 30° to 50° in increments of 8 cycles/h with the dual goal of decreasing pooled secretions that may lead to pneumonia and possibly preventing pressure ulcers. The pressure redistribution mattress also functions to reduce pressure-related skin damage. Percussion and vibration is denoted as “P&V” on the main menu and can be selected to improve pulmonary hygiene.

Removing the foot of the bed and placing the bed in a chair position can facilitate exiting the bed and encourages physical rehabilitation efforts.

Physical Examination in the ICU

Ella Illuzzi, RN, ANP-BC and Mark Gillespie, PA-C, MS

KEY POINTS

- 1 The key to a good physical exam in critically ill patients is the ability to interface medical technology with the patient's clinical presentation.
- 2 Performing both planned and quick focused (ie, unplanned or emergent) exams can make the difference in timely diagnosis and treatment, thus having a positive impact on patient outcome.
- 3 Acute and life-threatening situations in the intensive care unit are inevitable and timely examination is imperative. The initial visual assessment should take no more than 10 seconds.

The presence of advanced medical technology and sophisticated laboratory tests allow healthcare practitioners to provide the highest standard of care to patients particularly in the acute care setting. However, the importance of the physical examination should not be underestimated. The key to a good physical exam in the intensive care unit (ICU) setting is the ability to interface this medical technology with the patient's clinical presentation. Performing both planned and quick focused (ie, unplanned or emergent) exams can make the difference in timely diagnosis and treatment, thus having a positive impact on patient outcome.

Performing a physical exam in the ICU is often difficult. The bedside examination in an ICU may be hindered by various conditions. These include noisy alarms (eg, monitor, ventilator, IV pumps, etc), limited assessment due to sedation or analgesia, inability to easily change the patient's position, wounds, dressings and multiple invasive lines or tubes. Amid these obstacles, this exam should be performed quickly and efficiently. This chapter will demonstrate how to perform a physical examination on routine

assessment and in certain critical situations in the acute care setting.

PLANNED PHYSICAL EXAMINATION

Physical examination on daily rounds is a vital part of ICU management. Before performing a physical exam, review the patient's chart; obtain a history and gather information from the patient, relatives, medical staff, or review of notes. For all patients whether awake or unresponsive, it is best to begin the exam by introducing yourself and explaining what you intend to do. In the ICU, it is easy to divert attention from the patient and focus on the alarming monitors and machines. The main focus should remain on the patient's clinical presentation while integrating information from the monitors and diagnostic tests. The patient's current illness and status will prioritize the exam. Use a structured method to the examination by reviewing all major organ systems; this will avoid omitting important information. Accurate documentation of physical exam findings

will identify trends or any change in a patient’s clinical status.

Central Nervous System

Frequent evaluation of pain, sedation and delirium in the ICU is generally underestimated. There are various scales to assess level of sedation and pain and choosing 2 reliable scales, for example the Sedation-Agitation Scale (SAS)¹ (Table 10–1) to assess the level of sedation and the Wong-Baker FACES Pain Rating Scale² to communicate how much pain the patient is experiencing. In the ICU, most patients are unable to self-report pain or communicate, which makes this exam more challenging. If the patient cannot participate in this exam then look for signs of pain such as facial cues, restlessness/positioning, and/or physiological changes (rise in heart rate and blood pressure). However, vital signs are not used solely to assess for pain. Make note of the analgesic or sedative agent the patient is receiving, titrate and taper to maintain goal. In an adult ICU, light levels of sedation are recommended and daily interruptions can reduce the amount of time on a ventilator and the ICU stay.³

Critically ill patients may be obtunded, agitated, or delirious. For patients who are not sedated, assess whether they are alert and oriented. For critically ill patients, the cause in cognitive impairment can be variable and include, but is not limited to, metabolic

disturbances or medications such as analgesics and sedatives. According to the 2013 clinical practice guidelines for Pain, Agitation, and Delirium (PAD), delirium should be assessed daily in mechanically ventilated patients.⁴ Delirium can occur in nearly 60% to 80% of mechanically ventilated patients and is associated with increased mortality in the ICU and long-term cognitive impairment.⁴ Adult ICU patients can be assessed for delirium by using The Confusion Assessment Method for the ICU (CAM-ICU)⁵ (Figure 10–1).

Patients admitted to the ICU with intracranial pathology should have a more focused and detailed neurological assessment adjusted to their diagnosis and presentation. For all patients, pupils should be checked for size, equality, and reaction to light.

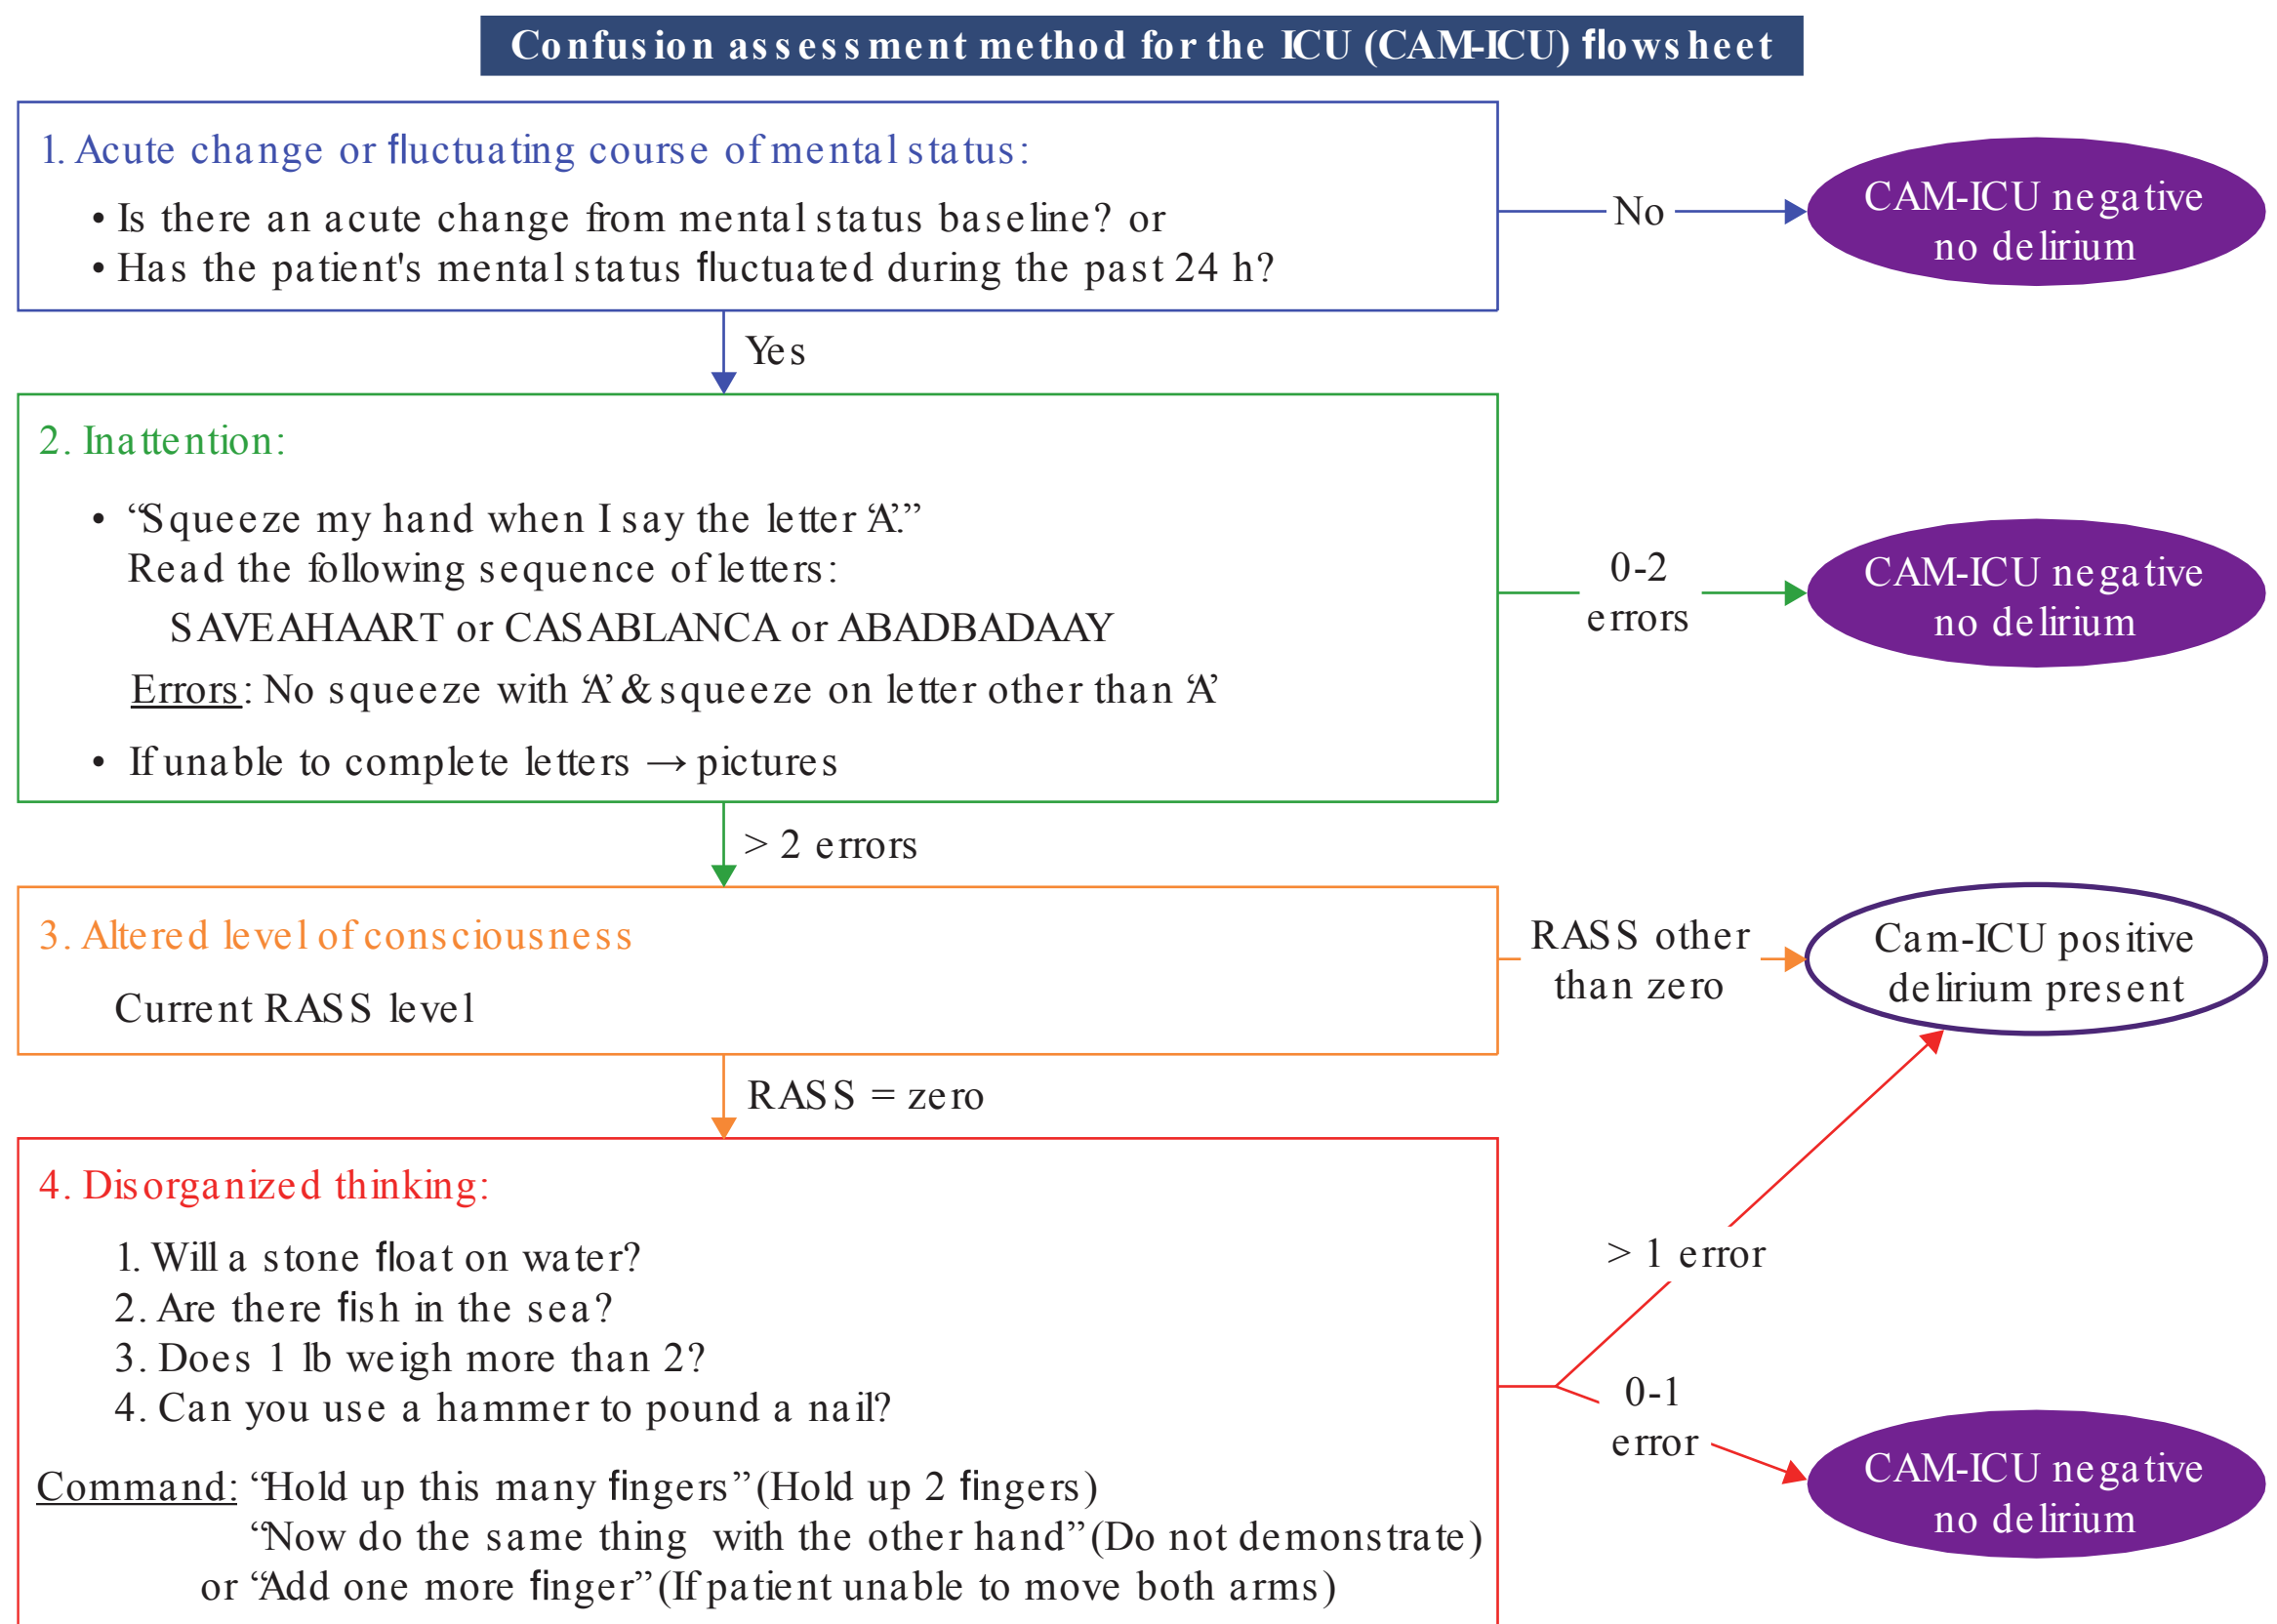

Respiratory System

Routine examination of the respiratory includes examining the airway and auscultating the lungs. Further evaluation includes inspecting the patient’s overall appearance, work of breathing, accessory muscle use, bilateral chest rise, oxygen saturation, and arterial blood gas findings. The patient may require supplemental oxygen and the decision for such support (nasal cannula, nonrebreathing mask, noninvasive, and invasive ventilation) should be based on clinical presentation and laboratory findings.

TABLE 10–1 Riker sedation-agitation scale.

Score	Term	Descriptor
7	Dangerous agitation	Pulling at ET tube, trying to remove catheters, climbing over bedrail, striking at staff, thrashing side-to-side
6	Very agitated	Requiring restraint and frequent verbal reminding of limits, biting ETT
5	Agitated	Anxious or physically agitated, calms to verbal instructions
4	Calm and cooperative	Calm, easily arousable, follows commands
3	Sedated	Difficult to arouse but awakens to verbal stimuli or gentle shaking, follows simple commands but drifts off again
2	Very sedated	Arouses to physical stimuli but does not communicate or follow commands, may move spontaneously
1	Unarousable	Minimal or no response to noxious stimuli, does not communicate or follow commands

FIGURE 10–1 CAM-ICU.⁵

For intubated and mechanically ventilated patients, examine the endotracheal tube (ETT) position both on exam (eg, 21 cm at the lips) and on chest x-ray (CXR) (eg, ETT tip 5 cm above the carina) and review the ventilator settings and the output information. Basic ventilator settings include the ventilator mode, respiratory rate, tidal volume, fraction of inspired oxygen (FiO_2) and positive end expiratory pressure (PEEP). Make note of the measured or output tidal volumes, minute volumes, flow rate and peak, and plateau pressures. Other parameters to include during respiratory examination are correlating the patient's current condition with their chest x-ray, lung sonogram (if available), and any chest tubes or drains. Most importantly, take this opportunity to assess the readiness of the patient's ability to wean off the ventilator, which should be the ultimate daily goal.

Cardiovascular System

An assessment of the cardiovascular system should be obtained which includes auscultation of heart sounds, evaluation of pulses, capillary refill, and edema. Most ICU patients are continuously monitored with beat-by-beat measurements via the electrocardiogram (ECG) and blood pressure (via noninvasive cuff or invasive arterial catheter monitor). Use this information and integrate it with the patient's clinical status. Observe the medications, especially continuous infusions that the patient is receiving such as inotropic agents, vasopressors and antiarrhythmic medications. A bedside transthoracic echocardiogram is relatively quick and useful in the evaluation of the right and left ventricular function and can guide the use of intravenous fluids, vasopressors, or other cardiac agents.

Abdomen

The routine abdominal exam is very important, owing to the fact that it tends to mask infection. The abdomen should be thoroughly examined by checking tenderness, distention, and bowel sounds. Pay close attention to any surgical incisional sites or wounds for erythema or other signs of infection or perforation, for example, purulent, enteric, or bilious drainage. Make note of any drains or stomas and trend the output volumes and color. If clinical findings are consistent with abdominal hypertension or compartment syndrome, then perhaps intraabdominal pressure measurements may be further warranted.

The patient's nutritional status should be addressed including daily weights and whether the patient's nutritional needs are being met. Bowel function should also be noted and the output recorded.

Renal

The necessity for an indwelling urinary catheter should be addressed daily. A patient on strict input and output measurements should have recorded urine output hourly. Note the type of fluid therapy the patient is receiving and whether the amount or rate is accurate or appropriate based on the patient's clinical status, weight, cardiac status, and sensible and insensible fluid losses. Daily laboratory trends in renal function should be monitored and if indicated, assess the need for renal replacement therapy.

Skin

Points of particular interest during this exam are the color of the skin (cyanosis or pallor), temperature, and presence of any rash. In patients that have indwelling catheters (ventriculostomy or lumbar drains) and vascular access (central or arterial catheters), examine these sites routinely for signs of infection and determine whether the catheter is still indicated based on the patient's clinical status. Check common sites such as bony prominences and the sacrum for decubiti ulcers or evidence of skin break down.

In addition to the physical exam, recent laboratory tests, microbiology findings, imaging results, and current medications should be reviewed frequently for appropriate management of the critical

care patient. [Table 10–2](#), modified from Runcie et al⁶ provides a quick guide for the physical examination.

UNPLANNED PHYSICAL EXAMINATION

Almost all ICU patients are continuously observed on cardiac and hemodynamic monitors, which is cornerstone of management in critically ill patients. Continuous observation of vital parameters such as heart rate, blood pressure, respiratory rate, and oxygen saturation allows the medical staff to stay apprised of any acute changes and the general condition of the patient.

Acute situations in the ICU are inevitable. In most instances, there are a plethora of possible diagnoses for a patient's presenting symptoms and time is of the essence. Therefore, thoughtful and timely examination is imperative. The following circumstances are frequent life-threatening conditions that may arise in the ICU that warrant immediate attention. A stepwise guide to follow upon reaching the bedside is provided below with the intent of offering a template that the reader may customize to their practice environment.

You Are Called to the Bedside for...

Acute Bradycardia

Visual examination—The first thing you do as you walk into the room is observe the patient, their overall condition (eg, level of distress) and whether or not they are on oxygen or mechanical ventilation. Glance at the monitor to assess the ECG rate and rhythm, arterial blood pressure, and waveform or the noninvasive blood pressure (NBP) reading (may need to be cycled), the pulse oximetry reading/waveform, and respiratory rate. This assessment should take less than 10 seconds.

Physical examination—Then look more closely at the patient and note the level of alertness and distress. Is the patient awake or unresponsive? Is the patient in no acute distress (NAD) or in distress? Quickly glance at the patient's skin and lips for signs of cyanosis. Manually check for a pulse. Does the monitor accurately reflect the patient's pulse and clinical condition? Is the patient showing signs and symptoms of hypoxia? Quickly auscultate the chest

TABLE 10–2 ICU guide for physical assessment.

System	Primary Variable	Interrelated or Secondary Variable
General	Overall appearance Acute distress Level of consciousness	Sedation
Central nervous system	Level of consciousness (SAS) Pain level (Wong-Baker Pain Scale) Neurologic function examination Focal neurologic examination CAM-ICU	Sedation Analgesia
Respiratory system	Physical examination Oxygen saturation Arterial blood gas (ABG) Ventilator settings Chest imaging (x-ray, CT scan, lung ultrasound)	Signs of respiratory distress Breath sounds Cyanosis (skin, lips) Chest drains/tubes FiO ₂ , PEEP, tidal volume, minute volumes, peak and plateau pressures, flow
Cardiovascular system	Physical examination EKG Echocardiogram Direct parameters	Assess tissue perfusion (mental status, skin temperature, capillary refill time, and urine output) Heart rate, arterial/noninvasive blood pressure
Abdomen	Abdominal examination GI function Nutrition	Tenderness, distention, bowel sounds Wounds/drains/stomas Nasogastric/orogastric tube output Bowel movements Enteral or parenteral feeding
Renal	Urine output and fluid status	Peripheral edema
Skin	Physical examination Color Temperature	Edema, rashes, pressure ulcers, vascular access sites, indwelling catheter sites Cyanosis, hemoglobin level, oxygen saturation Signs of infection
Catheters	Peripheral, central and arterial catheters, Foley catheter	
Tubes/drains	ETT, nasogastric/orogastric tube, chest tube, pigtail drain, Jackson-Pratt drain, Penrose drain, negative pressure wound therapy	
Laboratory/diagnostic tests		
Medications		

Data from Runcie CJ, Dougall JR. Assessment of the critically ill patient, Br J Hosp Med 1990;43(1):74-76.

for bilateral breath sounds and verify that the patient is receiving adequate oxygenation and ventilation. Is the patient on a ventilator or breathing spontaneously? If the patient is on a ventilator look for the following: What are the settings? Do the ventilator inputs (ie, tidal volume) match the outputs? Are the alarms going off? If so, which alarms- high pressure,

low pressure, and/or low tidal volume? What is the breathing pattern and are the ventilator waveforms synchronous or dyssynchronous? Also, is the patient receiving the set tidal volume? Does the patient's ETT or tracheostomy need to be suctioned?
Acute management—If the patient is awake and in NAD, spontaneously breathing, not hypotensive

and no complaints, obtain a 12 lead ECG and analyze rhythm, perform further testing if necessary, assess for drug-induced causes, and discontinue the offending medication depending on the diagnosis and clinical scenario. If the patient is stable continue to monitor and observe closely. However, if the patient is unstable and symptomatic with a change in mental status, hypotension, and complaints of chest pain, then treatment should focus on optimizing the patient's hemodynamic status by initiation of the Advanced Cardiovascular Life Support (ACLS) protocol for bradyarrhythmia and treat the underlying cause.

If the underlying cause is hypoxia and the pulse oximeter shows desaturation, patient-ventilator dyssynchrony and/or the ventilator is alarming, refer to the section on Acute Respiratory Distress.

Acute Tachycardia

Visual exam—The first thing you do as you walk into the room is observe the patient and their overall condition. Observe the oxygen-ventilator-patient interface (are they connected to oxygen or the ventilator?). Glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure, and waveform or NBP reading and the pulse oximetry reading. This assessment should take less than 10 seconds.

Physical examination—Connect the oxygen or ventilator if disconnected. At the same time observe the patient and note the level of alertness and distress. Is the patient awake or unresponsive? Is the patient in NAD or in distress? Manually check the pulse. Does the monitor accurately reflect the patient's pulse and clinical condition? Simultaneously, assess the skin: hypothermic/hyperthermic, poor skin turgor, cold, and clammy. Is the patient febrile and/or in shock (hypovolemic, cardiogenic, obstructive, or distributive)?

Acute management—Obtain a 12-lead ECG and analyze rhythm. Your management will depend on the rhythm and whether the patient is stable or unstable. If the patient is stable then proceed with further testing if necessary, discontinue, and/or adjust medications depending on the diagnosis and clinical scenario and treat the underlying cause. If the patient is unstable, initiate the ACLS protocol, prepare for synchronized cardioversion and further pharmacologic treatment.

Acute Hypotension

Visual examination—The first thing you do as you walk into the room is observe the patient, the oxygen-ventilator-patient interface (are they connected to oxygen or the ventilator?) and glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or the NBP reading, and the pulse oximetry reading. This assessment should take less than 10 seconds.

Physical examination—Connect the oxygen or ventilator if disconnected. Assess for accuracy of the blood pressure reading by checking cuff or arterial catheter placement. Note the mean arterial pressure and quickly check for signs of organ perfusion. At the same time, look at the patient and note their level of alertness and distress. Is the patient awake or unresponsive? Is the patient in NAD or in distress? Is there an arrhythmia associated with hypotension? Is the patient in shock (hypovolemic, cardiogenic, obstructive, or distributive)? Has the patient received any medications that can cause hypotension?

Acute management—If there is an arrhythmia associated with hypotension, obtain an ECG and analyze rhythm, perform further testing if necessary, assess for drug-induced causes, and discontinue the offending medication depending on the diagnosis and clinical scenario. If the patient is truly in shock, begin resuscitation and treatment of the underlying cause. Perform a bedside echocardiogram to evaluate right and left ventricular function and volume status to direct treatment.

Acute Chest Pain

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or NBP reading, and the pulse oximetry reading. This assessment should take less than 10 seconds.

Physical examination—At the same time, look at the patient and note the level of alertness and distress. Is the patient awake or unresponsive? Is the patient in NAD or in distress?

If the patient can participate in the exam: Follow OPQRST algorithm: Onset of the event, provocation or palliation, quality of pain, region and radiation, severity, and time.

Acute management—Obtain 12-lead ECG for rhythm assessment specifically to rule out ST-changes, new onset left bundle branch block, or any arrhythmia. If EKG is noted for ST-elevation myocardial infarction, obtain an immediate cardiology consultation for possible need of emergent percutaneous catheter intervention. Make note of any arrhythmia (stable or unstable rhythm). If the patient is unstable and presumed cardiac ischemic etiology, start necessary pharmacologic treatment and initiate the ACLS protocol if needed. If the cause of chest pain is less likely due to cardiac etiology then rule out chest etiology. Auscultate bilateral breath sounds, assess for bilateral chest rise and perform an ultrasound of the chest to evaluate lung sliding or B-lines. Other unstable etiologies of acute chest pain that need to be considered include thoracic aneurysm, pulmonary embolus, pneumothorax, and mediastinitis. If the patient is stable, consider ultrasound, computed tomography (CT) scan and/or ventilation perfusion scan of the chest. If a pneumothorax is present, determine if the patient is stable or unstable. If the patient is unstable and experiencing signs of obstructive shock, immediate intervention for decompression is warranted.

Acute Respiratory Distress (Not on a Ventilator)

Visual examination—The first thing you do as you walk into the room is observe the patient, are they connected to supplemental oxygen, if so what type? Then glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or the NBP reading, respiratory rate, and the pulse oximetry reading. This assessment should take less than 10 seconds.

Physical examination—Apply supplemental oxygen as needed. At the same time, look at the patient and note their overall appearance, level of consciousness, skin color (cyanosis), work of breathing, accessory muscle use, airway resistance, airflow, and ability to speak in full sentences or not. Auscultate the lungs for any adventitious sounds, which may include the following: wheezing (asthma, bronchospasm), rales, or stridor. Has the patient been recently extubated and not tolerating it well? Has the patient had any recent intervention that may have caused a pneumothorax? Is the patient high risk for

pulmonary embolism and experiencing any associated symptoms? Is the patient exhibiting signs of anxiety and agitation? Is there any known previous pertinent medical history that could be attributing to this distress?

Acute management—If there are no signs of imminent respiratory failure, you have some time to retrieve an arterial blood gas sample, review valuable laboratory results and diagnostic findings (CXR or CT Chest) and bedside lung ultrasonography to assess for lung sliding to rule out pneumothorax, B-lines to rule out fluid overload and pleural effusion. This will help provide a list of differential diagnoses for the patient's respiratory status.

There are multiple strategies to treating a patient in respiratory distress whether it is close observation, medication, supplemental oxygenation, the need for an advanced airway, or an emergent intervention (chest tube thoracostomy). The patient's clinical status and arterial blood gas findings will help guide the management decisions.

Acute Respiratory Distress (on a Ventilator)

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the ETT or tracheostomy tube making sure it is connected and not dislodged. Then look at the monitor to assess the ECG rate and rhythm, the arterial blood pressure waveform or the NBP reading, and the pulse oximetry reading. Quickly look at the ventilator, its waveforms (tidal volume, pressure, and flow) and make note of which ventilator alarms are being triggered. This exam should take less than 10 seconds.

Physical examination—At the same time, look at the patient and note the overall appearance, level of consciousness, skin color (cyanosis), work of breathing, accessory muscle use, airway resistance, and airflow, and if there is ventilator synchrony versus dyssynchrony. Auscultate the lungs for bilateral and any adventitious sounds.

The main focus should always be on the patient rather than solely the ventilator. If the patient is rapidly deteriorating or abruptly unstable, disconnect the patient from the ventilator and hand ventilate with a bag valve mask providing 100% oxygen and use a PEEP valve if the patient was receiving PEEP. If the patient is orally intubated with an ETT, note the

position of tube at lips or teeth. Check the cuff of the ETT and listen for a leak, if there is a leak, infuse air using an empty syringe to assess for adequate filling. Determine if the patient needs suctioning of their ETT from possible obstruction or mucous plug. If the patient has a tracheostomy, assess for adequate placement in airway, adequate cuff volume, and inner cannula for patency.

If there is enough time to troubleshoot the ventilator, observe the ventilator waveforms, settings and alarming parameters. The ventilator alarms that are being triggered will give insight to why the patient may be in respiratory distress. Common ventilator alarms are high pressure, low pressure, high/low minute volume, apnea, disconnection in the circuit, and high-exhaled tidal volume. Check the current settings: ventilator mode, tidal volume, respiratory rate, FiO_2 , PEEP, and inspiratory to expiratory ratio. Make note of the measured tidal volumes, minute volumes, and peak and plateau pressures.

High-pressure alarms may indicate the following: mucus plug, pneumothorax, mainstream intubation, obstructed ETT (patient biting or mucus plug), asynchrony, or abdominal compartment syndrome affecting ability of adequate ventilation.

Low-pressure alarms may indicate the following: air leak, extubation, tube, or ventilator disconnection; note that there are many areas on the ventilator circuit tubing that can allow for a disconnection and the tubing must be examined carefully fully along its path.

Acute Lethargy/Unresponsiveness

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or the NBP reading, and the pulse oximetry reading. This assessment should take less than 10 seconds.

Physical examination—At the same time, look at the patient and note the level of consciousness and/or distress. If there is no contradiction, gently rub the patient's sternum with a closed fist to stimulate the patient. This will help assess whether they are awake, alert, and able to move extremities. Quickly assess the patient's pulses, extremities, and respiratory status. If the patient is receiving any sedative or analgesic, discontinue the offending agent and

consider a pharmacologic reversal agent if indicated (flumazenil or naloxone).

Is there concern for hepatic encephalopathy or metabolic encephalopathy?

Is the patient in acute respiratory distress? Is the patient obtunded or experiencing signs of herniation?

Is the patient having a seizure? Assess pupillary response, eye movement, nystagmus, or spontaneous movement of bilateral eyes?

Is the patient exhibiting any signs or symptoms of a stroke (cerebral vascular accident/transient ischemic attack)? If the patient can cooperate with a neurological exam, assess for facial drooping, arm drift, and slurred speech.

Acute management—If the patient is unresponsive, unstable, or experiencing signs of a stroke, initiate the ACLS protocol. If the patient is obtunded or unable to protect their airway, then consider intubation and initiation of mechanical ventilation. If the patient is in respiratory distress, refer to the section above on acute respiratory distress. Support the patient and treat the underlying cause.

Seizure

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or the NBP reading, and the pulse oximetry reading. This assessment should take less than 10 seconds.

Physical examination—At the same time, look at the patient for abnormal movements or shaking and note the level of consciousness and/or distress. Perform a quick assessment of the patient's respiratory status. Some patients need an advanced airway for airway protection. Observe the type of seizure activity: partial seizure, tonic clonic seizure, grand mal seizure, or status epilepticus.

Acute management—Provide a safe environment and administer a first line agent, such as an intravenous benzodiazepine (lorazepam, midazolam, or diazepam). Do not place anything in the patient's mouth. Review current medications and possible side effects that may have precipitated the seizure. Obtain a neurology consultation. For ongoing status epilepticus, continue further seizure treatment and consider airway protection with intubation and mechanical ventilation.

Acute Extremity Symptom or Coolness

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the monitor to assess whether the vital signs are stable.

Physical examination—Is the patient in distress and experiencing severe pain, weakness, numbness, or paresthesias of the extremity? Is the patient at risk for ischemic limb or compartment syndrome? Does the patient have a history of vascular disease or recent vascular surgery in the affected extremity? Check for indwelling catheters (peripheral intravenous catheter and arterial catheters) that may cause vascular compromise. Has the patient any recent surgery or trauma to the affected extremity? Assess any surgical or nonsurgical dressings that may be compressing the area.

Perform a thorough assessment of the affected extremity's proximal and distal pulses, coolness and capillary refill. Consider using a doppler if the pulse is unable to be palpated.

Acute management—Remove any invasive catheter, dressing, cast or splint that may be compromising the extremity. For concerns of ischemia or compartment syndrome call the appropriate consult.

Acute Abdominal Distention

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or the NBP reading, and the pulse oximetry reading.

Physical examination—At the same time, look at the patient and note the level of alertness and distress. Is the patient awake or unresponsive, in NAD or in distress? Pay close attention to the patient's general appearance, examine for pain, and note any recent fevers. A patient with peritoneal irritation is likely to remain still, contrary to a patient with obstruction, who usually presents with restlessness. Assess the abdomen and skin. Has the patient had recent abdominal surgery? Recent large volume resuscitation? Risk for intra-abdominal bleeding? Recent anticoagulation and possible skin ecchymosis? Be sure to ask about the patient's last bowel movement or recent vomiting. Has the urine output abruptly decreased or was there a change in color? Does the patient have any intraabdominal surgical drains in

place and is there any fluid output? Are you having any difficulty ventilating the patient with oxygen? If the patient is on mechanical ventilation and experiencing respiratory distress and desaturation from inadequate ventilation, are the peak inspiratory pressures elevated? Is the patient experiencing signs of obstructive hypotension and shock?

Acute Management

If the patient is stable, consider an abdominal x-ray, CT scan, or surgical consult. Review medications that could be further potentiating an obstructive process or gastroparesis. Obtain an intra-abdominal pressure via bladder pressure measurement. If the etiology is primary abdominal compartment syndrome, immediate surgical intervention is required for abdominal decompression. For unstable patients, especially those experiencing signs of obstructive shock, provide adequate oxygenation, ventilation, and cardiovascular support.

Acute Anuria

Visual examination—The first thing you do as you walk into the room is observe the patient and glance at the monitor to assess the ECG rate and rhythm, the arterial blood pressure and waveform or the NBP reading, and the pulse oximetry reading.

Physical examination—At the same time, look at the patient and note their level of consciousness and/or distress. Check the Foley catheter for kinks and hand irrigate to assess patency. Evaluate the patient's volume status; is the patient volume depleted, hypoperfused, or has a low cardiac output? Is the patient hypotensive or in shock? Is there an obstruction? Is the patient exhibiting signs of acute renal failure?

Assess abdomen for distention, tenderness, rigidity, or a possible complication or failure of drains, such as an ileal conduit or nephrostomy tube. Obtain intra-abdominal pressures to rule out compartment syndrome. Review laboratory and chemistry information.

Acute management—If there is an indwelling urinary catheter, consider mechanical obstruction and frequently administer saline flushes to assure patency. Administer a fluid bolus challenge to assess the response to fluid. If the patient has oliguric or anuric acute renal failure further testing is required. Obtain a bedside renal ultrasound to assess for signs

of obstruction, for example, bladder distension and hydronephrosis. If a patient's clinical status is deteriorating, consider a nephrology consultation and possible initiation of renal-replacement therapy.

Imaging of the Critically Ill Patient: Radiology

Nida Qadir, MD and Roshen Mathew, MD

KEY POINTS

- 1 Chest radiography is particularly useful in the initial placement, positioning of invasive hardware, and for monitoring of complications postprocedure in critically ill patients.
- 2 Contrast imaging should be used judiciously in critically ill patients. Computed tomography (CT) with contrast helps further evaluation of lung parenchyma and pulmonary vascular lesions.
- 3 Atelectasis and pneumonia are common causes of respiratory failure in the intensive care unit (ICU). Unrecognized it can progress to cavitation and abscess formation.
- 4 High probability ventilation perfusion scans have good positive predictive value for Pulmonary Embolism, and is in par with CT Pulmonary Angiography which show intraluminal filling defects for the same.
- 5 Pulmonary edema and acute respiratory distress syndrome (ARDS) may have similar radiologic features but have a different time of onset, presentation, and its ensuing clinical progression.
- 6 Bedside ultrasound is a convenient option for the evaluation and drainage of the pleural space.

IMAGING PROCEDURES

Imaging is an essential tool in the clinical assessment and management of critically ill patients. Although bedside ultrasound and chest radiography are the mainstays of initial assessment, an extensive variety of imaging options are available to the physician in the ICU, including CT, magnetic resonance imaging (MRI), and nuclear medicine studies. Interventional procedures, either at the bedside or in the radiology suite, are also playing an increasingly important role in the management of critical illness.

The choice of a particular imaging modality is occasionally difficult and should be based on recommendations in the literature, local expertise, type of equipment available, and the experience of the radiologists. Given the increasing emphasis on cost-effective practice, clinicians and radiologists

must maximize the diagnostic and therapeutic yield of procedures while minimizing costs. The main indications, strengths, and weaknesses of imaging modalities used in common ICU scenarios are reviewed in this chapter. Although abdominal, neurologic, and musculoskeletal imaging studies play an important role in the care of the critically ill patient, this chapter will focus primarily on imaging of the chest and devices used in the ICU.

IMAGING TECHNIQUES

Plain Radiography

Portable chest radiographs are the most commonly requested imaging examination in the ICU. Despite their limitations, these films play an important role in the management of ICU patients. Chest radiographs

are used to identify and follow pulmonary and cardiac disorders as well as evaluate the positions of and complications from catheters and support devices used in the care of critically ill patients.

Imaging of the abdomen can also often begin with plain radiographs, which provide a readily accessible means of diagnosing perforation, bowel obstruction, and ileus. However, because the overall sensitivity of plain radiographs remains low, further imaging with CT is frequently necessary to confirm suspected pathology and to inspect the features of the bowel walls and surrounding fat. Supine radiographs are appropriate for verifying nasogastric or feeding tube placement and for initial investigation of renal stones and ileus or bowel obstruction. Additional views obtained with the patient in a semiupright or lateral decubitus position are used to show air-fluid levels in the gastrointestinal tract or free intraperitoneal gas and may be helpful in patients with suspected bowel perforation or obstruction.

Ultrasound

Ultrasound examination at the bedside in the ICU is relatively inexpensive and does not use ionizing radiation. In the thorax, ultrasound is useful in imaging lung consolidation, pleural-based masses and effusions, pneumothorax, and diaphragmatic dysfunction. It can identify complex or loculated effusions and be used as a guide to thoracentesis or thoracostomy tube insertion.

In the abdomen, ultrasound provides for rapid evaluation of hepatobiliary and genitourinary disease, as well as assessment of vascular structures such as the aorta and the inferior vena cava. Similar to its use in the thorax, ultrasound can be used for identification and qualitative assessment of intraperitoneal fluid, as well as a guide for paracentesis.

In addition to its use in pleural and peritoneal fluid aspiration, ultrasound can be used as a tool in a multitude of bedside procedures such as central line placement, pulmonary artery catheterization, biopsies, and drainage of fluid collections. Its use in cardiac and hemodynamic assessment is becoming increasingly important in critical care.

Computed Tomography

By virtue of multiplanar imaging capabilities and improved contrast resolution, multidetector CT

(MDCT) has been shown to be very valuable in increasing diagnostic accuracy and guiding therapeutic procedures for critically ill patients. MDCT allows for more rapid scanning of patients, with imaging of the entire chest, abdomen, and pelvis with thin sections during a single breath-hold. Such short acquisition times have facilitated the use of CT for evaluation of vascular disorders such as aortic dissection and pulmonary embolism. CT is a critical diagnostic tool for the evaluation of an acute abdomen and also allows for improved characterization of pulmonary diseases.

Transportation of the ICU patient to the CT scanner poses significant risks and requires a coordinated effort from hospital personnel, including ICU physicians and nurses, respiratory therapists, radiology technologists, and radiologists. Careful monitoring during transport and throughout the procedure is essential and should be performed by a dedicated team skilled in airway management and resuscitation.

Nuclear Scintigraphy

Nuclear scintigraphy has a number of applications in the critically ill patient. Myocardial perfusion and infarct scanning in cardiac disease, ventilation-perfusion scanning in patients with suspected pulmonary embolism, evaluation of gastrointestinal hemorrhage and acute cholecystitis, and localization of occult infection are among the most common indications for radionuclide imaging in the ICU patient.

Magnetic Resonance Imaging

MRI provides excellent differentiation of vascular and nonvascular structures without the use of intravenous contrast material or ionizing radiation and provides cross-sectional images in multiple planes. It is generally considered the single best imaging method for evaluation of the central nervous system (CNS), head and neck, liver, and musculoskeletal system. However, in many cases, MRI is not feasible in the evaluation of the critically ill patient because of interference caused by ferromagnetic monitoring devices, the difficulty of adequately ventilating and monitoring patients within the narrow MRI gantry, and long scan times. MRI may be appropriate

in selected diagnostic dilemmas if MR-compatible equipment and coordinated effort among caregivers can be arranged.

IODINATED CONTRAST AGENTS

Peripheral venous access, particularly in an antecubital or large forearm vein is the preferred route of contrast agent administration in imaging. The flow rate should be appropriate for the gauge of the catheter used; a 20-gauge or larger catheter is preferable for flow rates of 3 mL/s or higher. When peripheral access is difficult, existing central venous catheters (CVCs) may be considered, provided that certain precautions are followed. First, catheter placement should be confirmed prior to its use, and its integrity and patency should be checked before and after injection. Additionally, flow rates greater than 2.5 mL/s should be avoided in order to keep intraluminal pressures below most manufacturers' specified limits; this flow rate limitation may in turn produce a suboptimal study. Finally, contrast media should not be administered by a power injector unless permitted by the manufacturer's specifications because of the risk of catheter breakage. Hospital personnel should be knowledgeable about the specific catheters used at their institution and adapt their practice accordingly.

Adverse reactions to iodinated contrast agents occur at low rates but are encountered not infrequently given their widespread use. Idiosyncratic reactions range from benign urticaria to, very rarely, life-threatening hypotension, laryngeal edema, and bronchospasm. These events are not considered truly allergic in nature because they are not antibody mediated and are inconsistently reproducible with subsequent administrations. Prior allergy-like reaction to contrast media is associated with an up to 5-fold increased likelihood of the patient experiencing a subsequent reaction. A history of asthma or other allergic diatheses may also predispose individuals to reactions. The predictive value of allergy to shellfish, previously thought to be helpful, is now recognized to be unreliable.

In high-risk patients, pretreatment with steroids should be given beginning at least 6 hours prior to the injection of contrast media whenever possible. Supplemental administration of an H₁ antihistamine

(eg, diphenhydramine) may reduce the frequency of urticaria, angioedema, and respiratory symptoms. Although pretreatment with corticosteroids appears to be effective for mild events, no randomized controlled clinical trials have demonstrated premedication protection against severe life-threatening adverse reactions. In the latter situation, an alternative imaging modality such as MRI should be considered.

Contrast-induced nephropathy (CIN) is another important complication of intravascular iodinated contrast use. The most important risk factor for CIN is preexisting renal insufficiency. Multiple other predisposing factors have been proposed, including diabetes mellitus, dehydration, cardiovascular disease, advanced age, and exposure to multiple doses of iodinated contrast in a short time interval (< 24 hours), but these have not been rigorously confirmed as independent risk factors. There is no specific creatinine or estimated glomerular filtration rate (eGFR) level that absolutely precludes the use of contrast agents; the decision to use contrast must be made on a case-by-case basis, carefully weighing the need for the study in high-risk patients. The major preventive action against CIN is to ensure adequate hydration with isotonic fluid. Substitution of sodium bicarbonate for 0.9% saline or addition of N-acetylcysteine to intravenous hydration is controversial. Multiple studies and a number of meta-analyses have had disparate results and neither strategy can be definitively recommended.

If CIN does develop, its clinical course depends on a number of variables, including baseline renal function, coexisting risk factors, and degree of hydration. Serum creatinine usually begins to rise within 24 hours of intravascular iodinated contrast medium administration, peaks within 4 days, and often returns to baseline within 7 to 10 days. Progression to end-stage renal disease is exceptionally rare and usually develops in the setting of multiple risk factors.

IMAGING OF SUPPORT AND MONITORING DEVICES

Endotracheal and Tracheostomy Tubes

Both endotracheal intubation and tracheostomy may cause potentially serious complications. Malpositioning of the endotracheal tube (ETT) occurs

in approximately 15% of endotracheal intubations. The clinical assessment of tube location is frequently inaccurate, and a chest radiograph should be obtained immediately following intubation. With the neck in neutral position, the ideal position of the tube tip is 5 to 7 cm above the carina; flexion of the head and neck causes a 2-cm descent of the tip of the tube, whereas extension of the head and neck causes a 2-cm ascent of the tip. In 90% of patients, the carina projects between the fifth and seventh thoracic vertebrae on the portable radiograph; when the carina cannot be clearly seen, the ideal positioning of the ETT is at the T2-T4 level. The aortic arch also may be used to estimate tube location because the carina is typically at the level of the undersurface of the aortic arch. If the ETT is too high, there is a risk of either inadvertent extubation or hypopharyngeal intubation, which can cause ineffective ventilation, gastric distention, or vocal cord injury. If the ETT is too low, selective intubation of the right mainstem bronchus may occur, resulting in segmental or complete collapse of the left lung,

hyperinflation of the right lung, and possible pneumothorax (Figure 11–1). The balloon cuff should fill but not dilate the trachea. Cuff overinflation can cause tracheal injury, including tracheomalacia, tracheal stenosis, or acute tracheal rupture.

Inadvertent placement of the ETT into the esophagus is uncommon but may be catastrophic when it does occur. Esophageal intubation may be difficult to diagnose on the portable chest film because the esophagus frequently projects over the tracheal air column. Gastric or distal esophageal distention, location of the tube lateral to the tracheal air column, and deviation of the trachea secondary to an overinflated intraesophageal balloon cuff are radiographic signs of esophageal intubation. The right posterior oblique view with the patient's head turned to the right allows ease of separation of the esophagus and trachea and can be obtained in equivocal cases.

Tracheostomy is typically performed in the patient who requires relatively long-term ventilatory support. The tip of the tracheostomy tube should be

(a)

(b)

FIGURE 11–1 Right mainstem intubation. **A.** Placement of the endotracheal tube (arrow) into the right mainstem bronchus with resulting collapse of the left lung. **B.** Reexpansion of the left lung after retraction of the endotracheal tube.

located at approximately one-half to two-thirds of the distance from the stoma to the carina, and unlike the ETT's position, the tracheostomy tube's position is not changed by extension or flexion of the patient's head. Although small amounts of subcutaneous emphysema and pneumomediastinum may be seen after an uncomplicated tracheostomy tube placement, significant emphysema may be a sign of tracheal perforation. Pneumothorax can occur after tracheostomy tube placement and may also be a sign of tracheal perforation. Late complications include tracheal stenosis, stomal infection, aspiration, tube occlusion, and development of a fistula between the trachea and esophagus, pleura, or mediastinum. The fistula is caused by erosion through the posterior tracheal membrane and usually occurs at the level of the tracheal cuff. If the fistula develops below the level of the cuff, gastric contents may be aspirated into the lungs. If the fistula develops above the level of the cuff, gastric contents may collect in the upper trachea.

Central Venous Catheters

CVCs are used frequently in the ICU patient for venous access, monitoring central venous pressure, and hemodialysis. The subclavian, internal jugular, and femoral veins are the sites of venous access used most commonly; smaller-caliber central catheters can also be peripherally inserted via antecubital veins. CVCs inserted via a thoracic vein are visible on the chest radiograph, and knowledge of normal thoracic venous anatomy is required to assess catheter location. The subclavian vein originates by the lateral aspect of the first rib and courses posterior to the clavicle, and anterior to the first rib. The internal jugular vein courses vertically in the neck; its convergence with the subclavian vein to form the brachiocephalic vein usually occurs behind the sternal end of the corresponding clavicle. Whereas the right brachiocephalic vein has a vertical course as it forms the superior vena cava, the left brachiocephalic vein crosses the mediastinum from left to right in a retrosternal position to enter the superior vena cava. The superior vena cava is formed by the junction of the right and left brachiocephalic veins at the level of the first anterior intercostal space, with its upper border usually just superior to the angle of the right mainstem bronchus and the trachea. On a chest

radiograph, the junction of the superior vena cava and right atrium lies approximately 4 cm below the carina, or 1 to 2 cm below the superior right heart border. CVCs are optimally positioned when the tip within the superior vena cava, ideally slightly above the right atrium.

Appropriate catheter position must be verified radiographically, as malposition has been described in up to 40% of CVCs. Positioning of the catheter tip within the right atrium is common and may result in cardiac perforation and tamponade. Placement into the right ventricle may result in arrhythmias secondary to irritation of the endocardium or interventricular septum. A misplaced CVC may have its tip terminating in central systemic veins, which can result in inaccurate venous pressure readings as well as venous thrombosis or venous wall perforation. The most common location for a misplaced catheter entering the subclavian vein is the ipsilateral internal jugular vein. Less frequently, thoracic CVCs may enter the azygous, internal mammary, superior intercostal (Figure 11–2), thymic, left pericardiophrenic, or inferior thyroid veins. Looping, knotting, and kinking of the catheter may also occur (Figure 11–3), which can place mechanical stress on the vein and occasionally require removal by surgical or interventional radiology techniques.

Other complications of central venous catheterization include pneumothorax, hemothorax,

FIGURE 11–2 Placement of central venous catheter in the left superior intercostal vein (red arrow).

FIGURE 11–3 Chest radiograph showing a central venous catheter forming a loop in the left brachiocephalic vein and terminating in the subclavian vein (arrow).

and perforation, which may result in pericardial effusion, hydrothorax, mediastinal hemorrhage, or ectopic infusion of intravenous solutions (Figure 11–4). Less common complications include

air embolism and catheter fracture or embolism. Pneumothorax occurs in up to 5% of CVC insertions; the incidence of is higher with a subclavian approach than with an internal jugular approach. Pneumothorax may be clinically occult, and a chest radiograph should be obtained to exclude a pneumothorax following line placement. A radiograph should be obtained even following an unsuccessful attempted line placement.

Venous air embolism is an uncommon complication of central venous catheterization. Radiographically, air in the main pulmonary artery is diagnostic, but other features include focal oligemia, pulmonary edema, and atelectasis. Intracardiac air or air within the pulmonary artery is seen easily on CT.

Long-term complications of venous access devices include delayed perforation, pinch-off syndrome, thrombosis, catheter knotting, and catheter fragmentation. Left-sided catheters have a greater risk for perforation, with increased risk in catheters abutting the right lateral wall of the superior vena cava. In pinch-off syndrome, the catheter lumen is compromised by compression between the clavicle

(a)

(b)

FIGURE 11–4 Mediastinal hematoma following attempted central venous catheterization. **A.** Mediastinum appears unremarkable prior to catheter placement. **B.** Following attempted central line placement, there is widening of the superior mediastinum (arrows) secondary to mediastinal hemorrhage due to a lacerated subclavian artery. and the first rib, leading to catheter malfunction and possible catheter fracture. This is frequently first observed as subtle focal narrowing of the catheter as it crosses the intersection of clavicle and rib.

Pulmonary Artery Catheters

The pulmonary artery catheter (PAC) plays an important role in the hemodynamic monitoring of the critically ill patient. The catheter is inserted via the subclavian or internal jugular vein and its tip should lie within the right or left main pulmonary artery. The catheter tip should remain within 2 cm of the hilum so that it does not extend beyond the proximal interlobar arteries. Complications related to CVC insertion, such as pneumothorax, vascular injury, infection, and knotting, kinking, or coiling of the catheter may also occur with PAC insertion. Ventricular arrhythmias are also common during PAC insertion, though usually self-limited. Another major complication is pulmonary infarction (Figure 11–5), usually caused by peripheral migration and occlusion of the vascular lumen by the catheter, or by continuous wedging of the inflated balloon in a central pulmonary artery. The radiographic appearance of pulmonary infarction secondary to a PAC is similar to that of infarction from other causes and consists of a wedge-shaped

parenchymal opacity seen in the distribution of the vessel distal to the catheter. Management consists of removal of the catheter. Anticoagulation is generally not required, and resolution of consolidation usually occurs in 2 to 4 weeks.

Pulmonary artery rupture is a catastrophic complication of pulmonary artery catheterization, with a reported mortality rate of 46%. The incidence is low—no more than 0.2% of catheter placements. Risk factors include pulmonary hypertension, advanced age, and improper balloon location or inflation. The mortality rate increases in anticoagulated patients. Pseudoaneurysm formation has been reported secondary to rupture or dissection by the balloon catheter tip. This appears radiographically as a well-defined nodule at the site of the aneurysm, but it may be obscured initially by extravasation of blood into the adjacent air spaces. Chest radiographic findings often precede clinical manifestations, and death due to rupture of pseudoaneurysm may occur weeks following catheterization. The CT appearance of a pulmonary artery pseudoaneurysm has been described as a sharply defined nodule with a surrounding halo of faint parenchymal density. Pulmonary artery pseudoaneurysm now may be treated in some patients with transcatheter embolization rather than surgical resection.

FIGURE 11–5 Lung infarction secondary to pulmonary artery catheterization. **A.** Initial radiograph after catheterization shows the tip of the catheter at the level of the right interlobar pulmonary artery (arrows). Mild redundancy of the catheter is present within the dilated heart. **B.** At 24 hours, the patient developed hemoptysis. Radiograph now shows migration of the catheter into a segmental arterial branch (arrows) with increased density in the right lower lobe. **C.** Follow-up film demonstrates dense consolidation of the right middle and lower lobes secondary to infarction. (Reproduced with permission from Aberle DA, Brown K Radiologic considerations in the adult respiratory distress syndrome, Clin Chest Med. 1990 Dec;11(4):737-754.)

Intra-Aortic Balloon Counterpulsation

Intra-aortic balloon counterpulsation is used to improve cardiac function in patients with cardiogenic shock and in the perioperative period in cardiac surgery patients. The device consists of a fusiform inflatable balloon surrounding the distal portion of a catheter that is placed percutaneously from a femoral artery into the proximal descending thoracic aorta. The balloon is inflated during diastole, thereby increasing diastolic pressure in the proximal aorta and increasing coronary artery perfusion. During systole, the balloon is forcibly deflated, allowing aortic blood to move distally and decreasing the afterload against which the left ventricle must contract, thus decreasing left ventricular workload. The tip of the balloon ideally should be positioned just distal to the origin of the left subclavian artery at the level of the aortic knob (**Figure 11–6**). Complications occur in 8% to 36% of intra-aortic balloon pump (IABP) placements and are most often secondary to malpositioning of the catheter. Overadvancement of the catheter may cause occlusion of the left subclavian artery, resulting in arm ischemia, or obstruction of the left common carotid or left vertebral arteries, causing cerebral ischemia. Caudal placement of the catheter

FIGURE 11–6 Intra-aortic balloon pump positioned in the proximal descending thoracic aorta (red arrow). A pulmonary artery catheter is also seen with its tip located in the right main pulmonary artery (black arrow).

can obstruct renal or mesenteric arterial flow. Aortic dissection has been reported in 1% to 4% of IABP catheter insertions, and an indistinct aorta on chest radiographs has been suggested as an early clue to intramural location, requiring confirmation by angiography. Balloon leak or rupture with gas embolization has also been described as an extremely rare but potentially fatal complication.

Cardiac Pacemakers and Automatic Implantable Cardioverter-Defibrillators

Cardiac pacemakers can be inserted by 3 approaches: transvenous, epicardial, and subxiphoid. Most often the transvenous approach is used, whereby an introducer sheath is used to establish central venous access and allow for insertion of the pacing wire, which is then guided into the right ventricle under electrocardiogram (ECG), ultrasound, or fluoroscopic guidance. The right internal jugular and the left subclavian veins are often preferred, as these routes take advantage of the natural curve of the pacing catheter, allowing for smoother, more direct placement of the wire.

When viewed on a chest radiograph, the pacemaker lead should terminate in the right ventricular apex, slightly to the left of the thoracic spine and at the anterior-inferior aspect of the cardiac shadow. A lateral view can be obtained to confirm that the catheter courses anteriorly to the right ventricle if proper placement is in question. The pacemaker lead should curve gently throughout its course, as regions of sharp angulation will have increased mechanical stress and enhance the likelihood of lead fracture. Excessive lead length can result in myocardial perforation, causing hemopericardium and cardiac tamponade. Shorter leads can become dislodged and enter the right atrium. Leads also may become displaced and enter the pulmonary artery, coronary sinus, or inferior vena cava. Other complications include venous thrombosis or infection, either at the pulse generator pocket or within the vein.

Nasogastric Tubes

Nasogastric tubes are used frequently to provide nutrition and administer oral medications as well as for suctioning gastric contents. Ideally, the tip of the tube should be positioned at least 10 cm beyond the

gastroesophageal junction. This ensures that all side holes are located within the stomach and decreases the risk of aspiration.

Small-bore flexible feeding tubes have been developed to facilitate insertion and improve patient comfort. However, inadvertent passage of the nasogastric tube into the tracheobronchial tree is not uncommon, most often occurring in the sedated or neurologically impaired patient. In patients with endotracheal tubes in place, low-pressure, high-volume balloon cuffs do not prevent passage of a feeding tube into the lower airway. If sufficient feeding tube length is inserted, the tube actually may traverse the lung and penetrate the visceral pleura (Figure 11–7). Removal of the tube from an intrapleural location may result in tension pneumothorax, and preparations should be made for potential emergent thoracostomy tube placement at the time of removal. Other complications of nasogastric intubation include esophagitis, stricture, and, rarely, rupture of the pharynx, esophagus, or stomach.

In addition to feeding tubes, balloon tamponade tubes occasionally are used for nasogastric

intubation in the treatment of bleeding esophageal and gastric varices. The balloon can be easily recognized when distended, and correct positioning can be evaluated radiographically (Figure 11–8). Esophageal rupture complicates approximately 5% of cases in which balloon tamponade tubes are used.

Thoracostomy Tubes

Thoracostomy tubes (“chest tubes”) are used for the evacuation of air or fluid from the pleural space. When chest tubes are used for relief of pneumothorax (Figure 11–9), apical location of the tip of the tube is most effective, whereas a tube inserted to drain free-flowing effusions should be placed in the dependent portion of the thorax. Chest radiographs, ultrasound, or CT should be used to guide correct placement of the tube for adequate drainage of a loculated effusion. Failure of the chest tube to decrease the pneumothorax or the effusion within several hours should arouse suspicion of a malpositioned tube. Tubes located within the pleural fissures are usually less effective in evacuating air or fluid collections. An interfissural location is suggested by

(a)

(b)

FIGURE 11–7 Malpositioned feeding tube. **A.** Feeding tube courses via the right mainstem bronchus with the tip (arrow) overlying the right costophrenic angle. FIGURE 11-8 An abdominal radiograph showing placement of a Blakemore tube. The distal (gastric) balloon has been inflated.

orientation of the tube along the plane of the fissure on frontal radiographs and by lack of a gentle curvature near the site of penetration of the pleura, indicating failure of the tube to be deflected anteriorly or posteriorly in the pleural space. The lateral view may be confirmatory. Uncommonly, thoracostomy tubes may penetrate the lung, resulting in pulmonary laceration and bronchopleural fistula. Unilateral pulmonary edema may occur following rapid evacuation of a pneumothorax or pleural effusion that is of long standing or has produced significant compression atelectasis of lung.

CHEST RADIOGRAPHS IN THE INTENSIVE CARE UNIT: TECHNICAL CONSIDERATIONS AND UTILITY

Portable chest radiographs are frequently obtained in ICU patients. Almost all portable chest radiographs are taken with the patient supine and with the film placed behind the back of the patient (anteroposterior) rather than in the conventional upright, postero-anterior position used in the radiology department.

(a)

(b)

FIGURE 11-9 Pneumothorax. **A.** Development of a right-sided pneumothorax (black arrows) after placement of a subclavian central venous catheter (CVC). **B.** Reexpansion of the right lung after placement of a chest tube (red arrow).

Supine chest radiographs result in decreases in lung volume and can alter the size and appearance of the lungs, the pulmonary vasculature, and the mediastinum. Anteroposterior chest radiographs cause cardiac magnification, making evaluation of true cardiac size more difficult. Inspiratory films may be difficult to obtain because of respiratory distress, pain, sedation, or alterations in mental status. These technical limitations complicate diagnostic interpretation. Nonetheless, portable radiography continues to be a primary method of imaging critically ill patients.

Traditionally, routine daily chest radiographs have been performed on ICU patients, particularly those requiring mechanical ventilation. However, the benefit of this practice has recently been questioned. Multiple recent studies have found a low incidence of significant findings in routine radiographs, and no significant difference in mortality, length of stay, or ventilator days in patients receiving chest radiographs on a daily basis compared with those receiving chest radiographs for specific clinical indications. The American College of Radiology Thoracic Expert Panel concluded that chest radiographs should be obtained if there is a change in the clinical condition of the patient, or after placement of an ETT, central venous pressure or pulmonary artery catheter, chest tube, or nasogastric tube. Routine daily chest radiographs are not indicated.

ATELECTASIS

Atelectasis is one of the most common pulmonary parenchymal abnormalities seen in the ICU. It refers to collapse of previously inflated lung and results in diminished lung volume. The spectrum can be subtle, with only segmental or subsegmental involvement and minimal clinical significance, or extensive, with lobar involvement and ventilation-perfusion defects. Distinguishing atelectasis from pneumonia can be a challenge as the signs and symptoms often coexist. Atelectasis has a basilar predominance, particularly in the left lower lobe, and can be influenced by gravity. It also has a more rapid resolution than pneumonia.

Multiple factors contribute to the development of atelectasis. Hypoventilation results in atelectasis of the dependent lung in the bedridden patient. Bronchial obstruction from retained secretions cause

mucous plugging and may result in postobstructive collapse of the distal lung. A right mainstem bronchial intubation can cause atelectasis of the nonventilated left lung (see Figure 11–1). In postcardiac surgery patients, left lower lobe collapse occurs frequently due in part to the weight of the heart unsupported by pericardium, which compresses the left lower lobe bronchus. Central neurogenic depression, anesthesia, or splinting may decrease alveolar volume, reducing surfactant and promoting diffuse microatelectasis. Pleural processes, including pneumothorax and pleural effusion, may also result in compressive atelectasis.

Radiographic Features

The radiographic appearance of atelectasis depends largely on the degree and cause of lung collapse. Dependent (gravity-related) atelectasis occurring in supine patients may be demonstrated on thoracic CT even in healthy individuals but is usually not appreciated on plain chest radiography. Linear bands of opacity may be seen in “discoid” or “plate-like” atelectasis on a subsegmental level. Focal patchy opacities can be seen with atelectasis of lung subtended by a segmental bronchus. Lobar or lung collapse (Figure 11–10) results in a dense homogenous opacity of the involved lobes and radiologic signs of volume loss. These signs include displacement of fissures and the hila, mediastinal shift, deviation of the trachea, elevation of hemidiaphragm, and sometimes hyperexpansion of the uninvolved lung.

The left lower lobe is the most frequent location of lobar atelectasis, followed by the right lower lobe and right upper lobe. The radiographic features of left and right lower lobe collapse are similar and involve triangular opacities and silhouetting of the corresponding hemidiaphragm (Figure 11–10A). The right upper lobe also collapses into a triangular density, with superior and medial migration of the horizontal fissure, anterior migration of the oblique fissure, and silhouetting of the right superior mediastinum. Due to the lack of a horizontal fissure in the left lung, the left upper lobe collapses anteriorly; atelectasis in this region presents as a hazy opacification in the left upper lung zone that gradually fades inferiorly. Collapse of the lingula or right middle lobe usually results

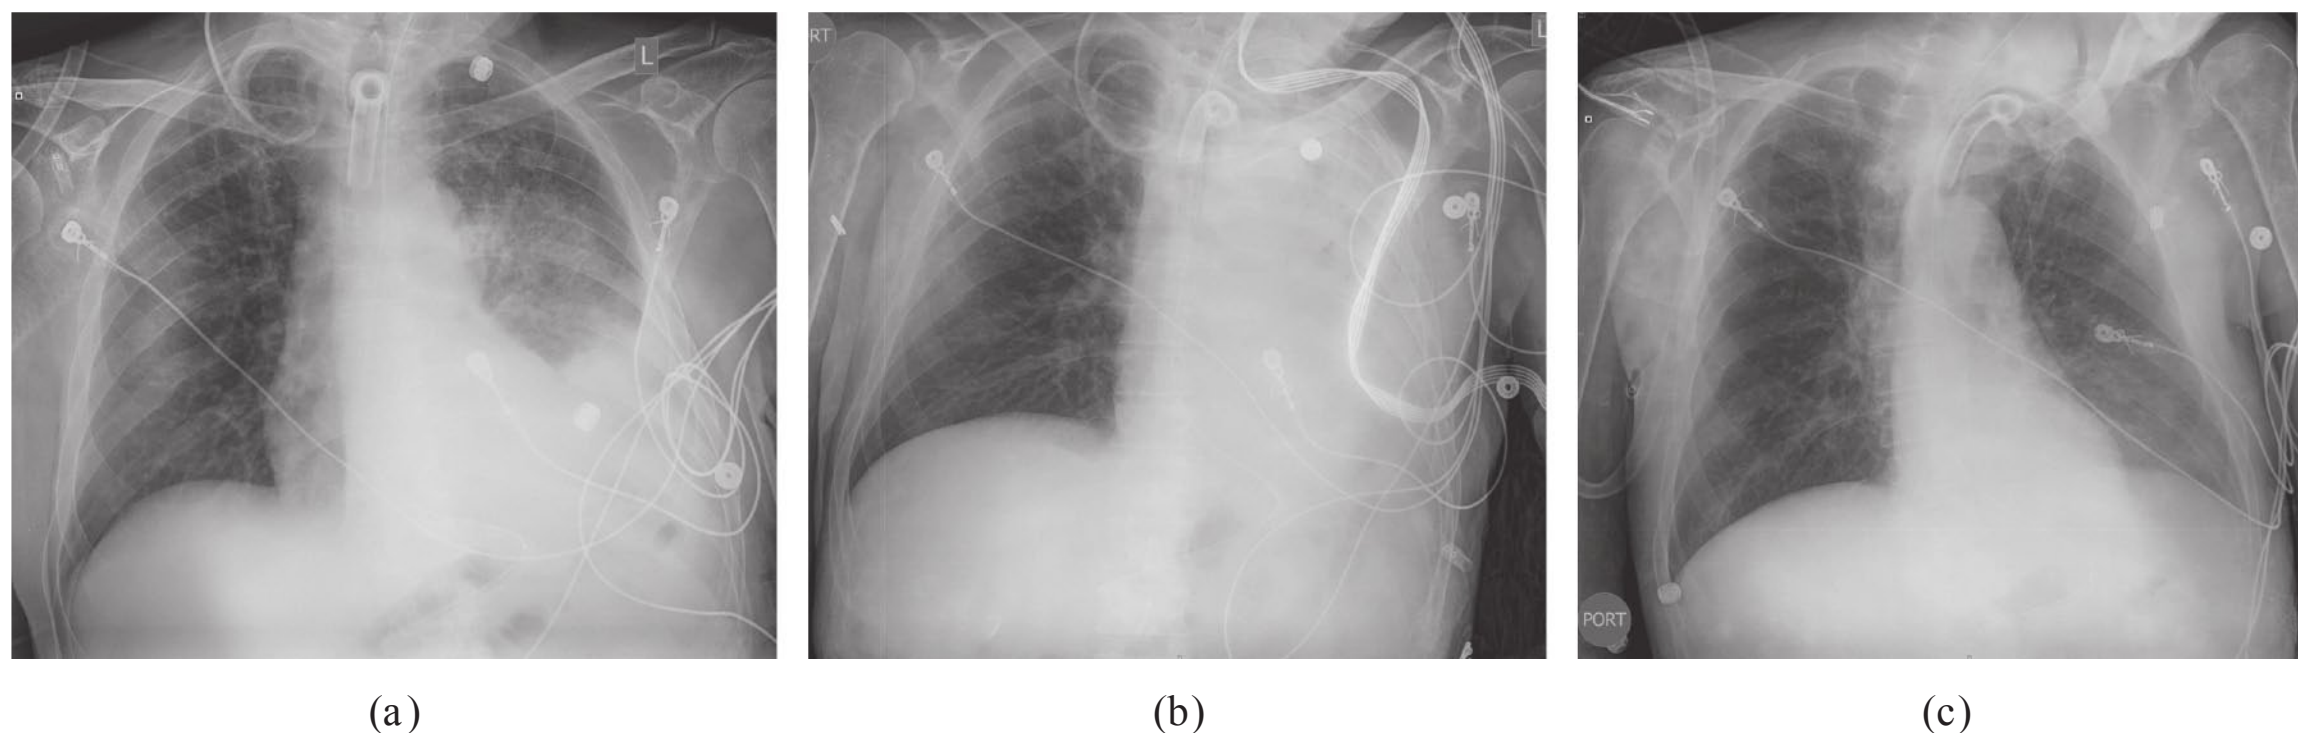

FIGURE 11–10 Lobar atelectasis. **A.** Collapse of the left lower lobe secondary to mucus plugging. **B.** Ongoing mucus plugging in the same patient resulting in collapse of the entire left lung. **C.** Reexpansion of the left lung after bronchopulmonary toileting.

in obscuring of the corresponding heart border but causes minimal signs of volume loss.

PNEUMONIA

Patients with severe pneumonia complicated by sepsis, respiratory failure, hypotension, or shock are seen frequently in the ICU. While many patients will have acquired pneumonia outside of the hospital, a substantial number will have nosocomial pneumonia, defined as lower respiratory tract infection occurring more than 48 hours after admission. Nosocomial pneumonia is the second most common nosocomial infection in the United States and is associated with high morbidity and mortality. Factors contributing to the high incidence of nosocomial pneumonias include endotracheal intubation or tracheostomy, prolonged mechanical ventilation, aspiration, and impaired host defenses. Inappropriate use of antimicrobials and emerging patterns of resistance has created additional treatment challenges.

Most radiologists sort the radiographic appearance of pneumonia into 3 categories that may aid in differentiation: lobar (alveolar or air space) pneumonia, lobular pneumonia (bronchopneumonia), and interstitial pneumonia. Lobar pneumonia is characterized on x-ray by relatively homogeneous regions of increased lung opacity and air bronchograms. The entire lobe does not need to be involved, and since the airways are not primarily involved, volume loss is not a frequent finding. *Streptococcus pneumoniae* is the classic lobar pneumonia, although other organisms produce a similar pattern. Lobular

pneumonia (bronchopneumonia) results from inflammation involving the terminal and respiratory bronchioles. The distribution is more segmental and patchy-appearing, affecting some lobules while sparing others. Mild volume loss may also be present. The most common organisms producing typical bronchopneumonia are *Staphylococcus aureus* and *Pseudomonas* species. Interstitial pneumonia is typically caused by viruses, *Mycoplasma pneumoniae* or, in immunocompromised patients, *Pneumocystis jiroveci*. Chest radiographs demonstrate an increase in linear or reticular markings in the lung parenchyma with peribronchial thickening.

Radiographic Features

Plain Films

The chest radiograph assesses for the presence and extent of pneumonia, as well as the existence of associated complications such as parapneumonic effusions, pneumatoceles, cavitation, and abscess formation. It also helps to gauge response to antibiotic therapy. A persistent pneumonia on the radiograph despite adequate therapy may raise suspicion for mimics of infectious pneumonia, including cryptogenic organizing pneumonia or bronchioalveolar carcinoma, or the presence of an obstructing mass.

The silhouette sign on the chest radiograph is useful for determining the site of pneumonia. When consolidation is adjacent to a structure of soft tissue density (eg, the heart or the diaphragm), the margin of the soft tissue structure will be obscured by the opaque lung. Thus, a right middle lobe consolidation

may cause loss of the margin of the right heart border, lingular consolidation may cause loss of the left heart border, and lower lobe pneumonia may obliterate the diaphragmatic contour.

Cavitation and abscess formation are also important complications of pneumonia caused by necrosis of the pulmonary parenchyma. Typical causative agents include anaerobes and gram-negative organisms, but cavitation can also be caused by staphylococci, *Mycobacterium tuberculosis*, atypical mycobacteria, and fungi. Lung abscesses may also be polymicrobial. Complications of lung abscess include sepsis, cerebral abscess, hemorrhage, and spillage of contents of the cavity into uninfected lung or pleural space. A lung abscess usually appears as a rounded, focal mass with a thickened (5–15 mm), irregular wall and an air-fluid level. An air crescent sign (crescentic radiolucency around lung parenchyma) or a halo sign (pulmonary opacity surrounded by a zone of ground-glass attenuation) may also be present (Figure 11–11). Abscesses may be surrounded by adjacent parenchymal consolidation (Figure 11–12) or appear as areas of lucency within an area of consolidation.

FIGURE 11–11 Pulmonary aspergillosis with cavitation. Chest radiograph demonstrates a pulmonary opacity surrounded by a zone of ground-glass attenuation (halo sign, white arrow) and a crescent-shaped air density surrounding a parenchymal opacity (crescent sign, red arrow).

(a)

(b)

(Reproduced with permission from Bongard FS, Sue D, Vintch J: *Current Diagnosis and Treatment Critical Care*, 3rd edition. New York: McGraw-Hill Education; 2008.)

Pneumatocoles (Figure 11–13) are associated with pneumonia and are caused by alveolar rupture and resulting formation of subpleural air collections. Radiographically, they appear as single or multiple

FIGURE 11-13 Pneumatocele in *Staphylococcus pneumonia*.

cysts with thin, smooth walls that often change in size and location on serial imaging. The most common causative agent is *S aureus*. Complications include pneumothorax and secondary infection.

Computed Tomography

The cross-sectional imaging plane and superior contrast resolution make CT useful in the evaluation of complicated inflammatory diseases. Cavitation,

which may be obscured on plain films, is easily identified on CT.

Localization of parenchymal diseases facilitates the direction of invasive studies such as bronchoscopy or open lung biopsy. Superimposed pleural and parenchymal processes are more easily differentiated on CT than on plain films (Figure 11-14). The administration of intravenous contrast material can further facilitate the differentiation of pleural and parenchymal disease; pleural lesions will exhibit little to no enhancement with contrast, whereas parenchyma will demonstrate enhancement as well as the presence of blood vessels.

ASPIRATION

Aspiration results from inhalation of oropharyngeal or gastric secretions into the larynx or lower respiratory tract. Aspiration can result in multiple pulmonary syndromes, including aspiration pneumonitis, a chemical injury caused by the inhalation of gastric contents, or aspiration pneumonia, an infectious process in which oropharyngeal secretions colonized by pathogenic bacteria are inhaled, resulting in lower respiratory tract infection. Several clinical conditions predispose patients to aspiration. Depressed levels of consciousness secondary to medications, seizures,

FIGURE 11–15 Aspiration following drug overdose. Multiple areas of pulmonary opacification are present bilaterally. (Reproduced with permission from Bongard FS, Sue D, Vintch J: *Current Diagnosis and Treatment Critical Care*, 3rd edition. New York: McGraw-Hill Education; 2008.)

drug overdose, anesthesia, or neurologic disease result in impaired upper airway reflexes ([Figure 11–15](#)). Mechanical factors predisposing patients to aspiration include endotracheal intubation, enteral feeding tubes, gastric distention, vomiting, gastroesophageal reflux, and decreased esophageal and gastrointestinal motility. Pneumonia can develop when oral or gastric secretions contaminated with bacteria are aspirated. Poor oral care may result in bacterial colonization of oropharyngeal secretions. Although gastric acidity maintains sterility of stomach contents in normal circumstances, antacid therapy for stress ulcers prophylaxis increases gastric pH, which may result in gastric colonization with pathogenic bacteria. Enteral feedings, small bowel obstruction, and gastroparesis may also result in bacterial colonization of gastric contents.

Radiographic Features

The radiographic pattern seen in aspiration depends on the position of the patient, as well as the volume and the nature of aspirated contents. In a supine patient, the posterior segments of the upper lobes and superior segments of the lower lobes are typically affected. In a semirecumbent or upright patient, the basilar segments of the lower lobes are usually involved. The right lung is more frequently involved

than the left due to the larger caliber and straighter course of the right mainstem bronchus.

Aspiration of small amounts of water or neutralized gastric content may produce minimal air-space opacities that rapidly resolve. If acidic gastric contents are aspirated (Mendelson syndrome), air-space disease rapidly develops, and can resemble pulmonary edema if the amount of aspirate is massive. Aspiration of bacteria resulting in pneumonia will produce infiltrates in characteristic bronchopulmonary segments; bilateral and multilobar consolidation may occur. Complications result from parenchymal necrosis and include the development of cavitary disease, empyema, or lung abscess.

PULMONARY EMBOLISM

Pulmonary embolism (PE) is a common, life-threatening disorder that results from venous thrombosis, usually arising in the deep veins of the lower extremities. The signs and symptoms of pulmonary embolism are nonspecific, and can be seen in a variety of pulmonary and cardiovascular diseases. The clinician must stay alert to the possibility of pulmonary embolism in any patient at risk for Virchow triad of venous stasis, intimal injury, and hypercoagulable state. A variety of imaging resources, including chest radiography, ventilation-perfusion scans, pulmonary angiography, and spiral or helical CT, play a role in the diagnosis of pulmonary embolism.

Radiographic Features

Chest Radiograph

The chest radiograph is often abnormal but rarely, if ever, diagnostic of PE. Common findings can include cardiomegaly, pulmonary artery enlargement, atelectasis, and pleural effusion. Less frequently, Westermark sign (focal oligemia distal to the site of PE), or Hampton hump (wedge-shaped peripheral consolidation resulting from infarction, [Figure 11–16A](#)) may be seen, but these are also poor predictors of PE. Consequently, the role of the chest radiograph in PE is mainly limited to ruling out other diagnoses and aiding in the interpretation of the ventilation-perfusion radionuclide scan.

Ventilation-Perfusion Lung Scan

Ventilation-perfusion scans are based on the premise that pulmonary thromboembolism results in a region of lung that is ventilated but not perfused. The study consists of two scans—the perfusion scan and the ventilation scan—that are compared for interpretation. The perfusion scan involves injection of technetium-99m-labeled macroaggregated albumin. This agent is trapped via the precapillary arterioles and identifies areas of normal lung perfusion; regions of the lung with absent perfusion will appear photon deficient. The ventilation scan is performed by obtaining images after having the patient inhale a radioactive gas (xenon) or radioaerosol (technetium-99m diethylenetriamine penta-acetic acid). Perfusion and ventilation images are compared; perfusion defects in areas of normal ventilation are suggestive of pulmonary embolism.

Although the concept behind V/Q scanning is simple, image interpretation is complex and has several limitations in ICU patients. V/Q scanning must be done in conjunction with a chest radiograph, as perfusion abnormalities may have many etiologies other than PE, including chronic obstructive pulmonary disease (COPD), pulmonary edema, lung mass, pneumonia, and atelectasis, all frequently seen in ICU patients. Additionally, the reliability of radionuclide inhalation in intubated patients is unclear. Finally, while normal and high-probability V/Q scans have high negative and positive predictive values for PE, respectively, many V/Q scans are interpreted as intermediate- or low-probability and require further diagnostic testing.

CT Pulmonary Angiography

Ventilation-perfusion imaging has been largely replaced by multidetector computed tomography pulmonary angiography (CTPA), which is the current standard of care for detecting PE. Based on data obtained from the prospective investigation of pulmonary embolism diagnosis (PIOPED) II study, CTPA has a sensitivity of 83% and specificity of 96% in the diagnosis of pulmonary embolism. When CTPA was combined with CT venography (CTV), the sensitivity increased to 90% without significant changes in specificity. Data from PIOPED II also demonstrated high concordance between lower limb compression ultrasonography (CUS) and CTV

in the detection of lower extremity deep venous thrombosis (DVT); use of CUS obviates the additional radiation exposure associated with CTV.

CT findings of pulmonary embolism (Figure 11–16B) include the following:

- Intraluminal filling defects that sharply interface with intravascular contrast material.

(a)

(b)

FIGURE 11–16 Pulmonary embolism. **A.** Chest radiograph shows a wedge-shaped, peripheral consolidation, known as Hampton hump. **B.** CT scan revealing bilateral intraluminal filling defects.

- Complete arterial occlusion resulting in dilation of the artery in comparison with the adjacent bronchus.
- Partial filling defects surrounded by contrast. These may manifest as the “rim sign” in the axial plane or the “railway track sign” in the long axis of a vessel.
- Partial eccentric intraluminal filling defects making an acute angle with the arterial wall.

Of note, small subsegmental filling defects must be seen definitively in more than one axial image in order to be considered consistent with PE. Other nonspecific CT findings include ground-glass opacities consistent with pulmonary hemorrhage, wedge-shaped consolidations resulting from pulmonary infarction and pleural effusions. Oligemia of lung parenchyma distal to the occluded vessel may be present. Signs of right ventricular dysfunction, such as right ventricular dilatation or leftward deviation of the interventricular septum, may also be present.

Pitfalls in the interpretation of CTPA include breathing artifact, inadequate contrast opacification of the pulmonary arteries, and suboptimal visualization of obliquely oriented vessels (eg, segmental branches of the right middle lobe and lingula). Partially opacified veins may be confused with thrombosed arteries; hilar lymph nodes and mucus-filled bronchi may be misinterpreted as thrombi. Flow- and motion-related artifacts can also result in false-positive findings.

Pulmonary Angiography

Pulmonary angiography is an invasive test and is considered the gold standard for the diagnosis of pulmonary embolism. Angiography is indicated when the pretest probability for PE is high and the results of CT angiography and V/Q show conflicting or indeterminate results. It also may be useful when therapy involves more complicated treatment such as an inferior vena cava filter, surgical embolectomy, or thrombolytic therapy.

Pulmonary angiography requires the percutaneous placement of an intravascular catheter through the femoral vein, past the right ventricle and into the pulmonary artery. Contrast is then injected at a rapid rate and images are acquired. A filling defect or abrupt cutoff of a small vessel is indicative of an

embolus in this study. Other nonspecific findings may include decreased perfusion, delayed venous return, abnormal parenchymal stain, and crowded vessels. Complications of pulmonary angiography are frequently related to catheter insertion and manipulation and include arrhythmias, heart block, cardiac perforation, right-sided heart failure, and cardiac arrest.

Magnetic Resonance Angiography

The PIOPED III study investigated the diagnostic accuracy of gadolinium-enhanced magnetic resonance angiography (MRA) alone or in combination with venous phase magnetic resonance venogram (MRV) for the diagnosis of PE. The sensitivity and specificity of MRA was 78% and 99%, respectively; combined MRA/MRV had a sensitivity of 92% and specificity of 96%. However, due to an unacceptably high percentage of patients with technically inadequate examinations, the investigators recommended that MRA only be performed in centers with significant pulmonary MRA experience and in patients with contraindications to all other standard tests.

SEPTIC PULMONARY EMBOLISM

General Considerations

Septic pulmonary emboli occur as a result of infections of the right side of the heart or of the peripheral veins. Major risk factors include intravenous drug use, indwelling catheters, and skin and soft tissue infections. Oropharyngeal infections can result in infectious thrombophlebitis of the internal jugular vein (Lemierre's syndrome), a rare but significant cause of septic pulmonary emboli. Most patients with septic pulmonary emboli have positive blood cultures at the time of imaging, with *S aureus* being the most commonly isolated organism.

Radiographic Features

The radiographic features of septic pulmonary emboli include multiple wedge-shaped or rounded peripheral opacities of varying size and lower lobe predominance, reflecting increased blood flow to dependent portions of lung. Cavitation is common, with necrotic debris often present within cavities.

(a)

(b)

FIGURE 11–17 Septic pulmonary embolism. **A.** CT scan demonstrating a feeding vessel leading to a peripheral nodule (arrow). **B.** Multiple cavitary lesions varying in size.

Hilar and mediastinal lymphadenopathy can occur, as can empyema.

CT imaging may detect disease earlier than the plain radiograph and better characterize its extent. In addition to the above findings, CT may also reveal peripheral nodules with feeding vessels and contrast enhancement of wedge-shaped lesions ([Figure 11–17](#)).

PULMONARY EDEMA

General Considerations

Pulmonary edema—an excess of water in the extravascular lung space—is a frequent cause of respiratory distress in the critically ill patient. According to Starling law, fluid accumulates in the extravascular space in one of two ways:

- Increased hydrostatic pressure within the lung capillaries (cardiogenic pulmonary edema), resulting from fluid overload or cardiac dysfunction.
- Increased capillary membrane permeability (noncardiogenic pulmonary edema), which

can be caused by a variety of insults to the microvasculature of the lung.

In the ICU patient, more than one mechanism may contribute to the formation of edema, increasing the difficulty of diagnostic interpretation on radiographs.

Radiographic Features

The earliest sign of cardiogenic pulmonary edema is vascular redistribution, manifested as hyperperfusion of the upper lobes, or cephalization. This finding is best seen in an upright film and may be difficult to see in the supine or semiupright films obtained in critically ill patients. As hydrostatic pressure increases, fluid accumulates in the interstitium; corresponding radiographic signs may be present prior to the onset of symptoms and include Kerley lines, peribronchial cuffing, loss of vascular definition, thickening of the fissures, and pleural effusions ([Figure 11–18](#)). Kerley A lines represent distension of anastomotic channels between lymphatics and appear as long, irregular linear opacities extending from the hila to the periphery. Kerley B lines are caused by edematous interlobular septa and are short, horizontal lines

FIGURE 11–18 Chest radiograph displaying multiple signs of cardiogenic pulmonary edema, including pleural effusions, cardiomegaly, prominent pulmonary vasculature (red arrow), Kerley B lines extending to periphery (yellow arrow), and peribronchial cuffing (blue arrow). A widened vascular pedicle is marked by the dotted line. (Reproduced with permission from Bongard FS, Sue D, Vintch J: *Current Diagnosis and Treatment Critical Care*, 3rd edition. New York: McGraw-Hill Education; 2008.)

found predominantly at the lung bases. Kerley C lines are reticular opacities primarily seen at the lung bases and signify thickened interlobular septa in transverse orientation. Kerley B lines are seen more frequently than Kerley A or C lines. Peribronchial cuffing results when fluid-thickened bronchial walls become visible producing rounded, “doughnut-like” densities in the lung parenchyma.

As extravascular fluid continues to accumulate, alveolar edema develops. Clinical signs and symptoms of heart failure are generally apparent at this point, and the chest radiograph will reveal airspace opacities that can coalesce into diffuse consolidations, frequently with a perihilar or basilar distribution. Air bronchograms are usually absent, and the lung periphery is often spared, sometimes resulting in a “batwing” appearance. In general, cardiogenic pulmonary edema is bilateral and symmetric, but atypical edema patterns may be seen in patients with underlying lung disease or as a consequence of gravitational forces related to patient positioning. Destruction of the lung due to emphysema may cause a patchy, asymmetric distribution of edema that spares regions of bullous disease.

FIGURE 11–19 Noncardiogenic pulmonary edema. The chest radiograph displays bilateral asymmetric air space opacities. There are no pleural effusions. The heart and vascular pedicle are of normal size. (Reproduced with permission from Bongard FS, Sue D, Vintch J: *Current Diagnosis and Treatment Critical Care*, 3rd edition. New York: McGraw-Hill Education; 2008.)

Widening of the vascular pedicle is also seen in cardiogenic pulmonary edema. The vascular pedicle width extends from the superior vena cava on the right side of the mediastinum to the proximal descending aorta on the left. Vascular pedicle width greater than 7 cm is consistent with volume overload.

Distinguishing cardiogenic from noncardiogenic pulmonary edema is not always possible radiographically, and the 2 processes may be seen concurrently in ICU patients. In noncardiogenic pulmonary edema ([Figure 11–19](#)), the vascular pedicle width tends to be normal, and pleural effusions, septal thickening, and peribronchial cuffing are absent. Edema is more likely to be patchy and peripheral in distribution, in contrast to the central or basilar distribution seen in cardiogenic pulmonary edema.

ACUTE RESPIRATORY DISTRESS SYNDROME

General Considerations

ARDS is a diffuse, acute, inflammatory lung injury manifested by severe hypoxia and bilateral radiographic infiltrates of noncardiogenic etiology. It

can result from either direct pulmonary injury or in response to a systemic insult. Imaging plays an important role in the diagnosis of ARDS and may help determine its underlying etiology.

Radiographic Features

The radiographic manifestations correlate with the pathologic changes seen in the lung parenchyma and vary with the stage of lung injury. There are 3 phases of ARDS as described below:

- **Exudative phase (days 1-7):** This phase is characterized by endothelial and epithelial injury and an influx of protein-rich fluid, first into the interstitium and subsequently into the alveoli. Alveolar atelectasis and hyaline membrane formation are seen. Radiographically, interstitial edema is initially seen, followed by alveolar consolidation; both patterns may be present concurrently (Figure 11-20A). Additionally, if a direct lung injury such as pneumonia was the trigger for ARDS, its presence may be evident.
- **Proliferative phase (days 8-14):** Infiltration with fibroblasts and type II pneumocytes occurs in this phase as a response to injury and coarse reticular opacities may develop on the chest radiograph. Imaging will otherwise remain relatively static, as alveolar and interstitial edema will persist. The development of additional airspace opacities should generate concern for new infection or other complications.

(a)

(b)

FIGURE 11-20 ARDS. **A.** Exudative phase of ARDS. CT demonstrates bilateral consolidations with air bronchograms and interstitial edema. **B.** Fibrotic phase of ARDS. CT reveals traction bronchiectasis and honeycombing.

- **Fibrotic phase (day 15 onward):** This late phase of ARDS may overlap with the proliferative phase and is characterized by collagen deposition and fibrosis. The degree of fibrosis is variable and the radiographic findings can range from complete resolution to the development of widespread reticular markings, cysts, airway distortion, and persistent ground-glass opacities (Figure 11-20B).

PLEURAL EFFUSION

General Considerations

Pleural fluid is primarily formed on the parietal pleural surface and absorbed on the visceral pleural surface. Approximately 25 mL of fluid is normally present in the pleural space. When there is an imbalance between production and absorption of pleural fluid, excess intrapleural fluid accumulates and pleural effusions form. While the plain chest radiograph can be useful for detecting and estimating the amount of pleural effusion, pleural fluid is more easily visualized and distinguished from lung parenchyma with CT or bedside ultrasound. The role of ultrasound in visualizing pleural effusions is detailed in Chapter 12.

Radiographic Features

The appearance and distribution of fluid within the pleural space is greatly affected by lung elastic recoil

(a)

(b)

FIGURE 11–21 Pleural effusion. **A.** Chest radiograph displaying a left-sided pleural effusion with a meniscus sign. **B.** Massive left pleural effusion with rightward tracheal deviation.

and gravity. On erect frontal and lateral radiographs, free pleural effusions typically have a concave, upward-sloping interface with the lung (the meniscus sign) and result in blunting of the costophrenic angle ([Figure 11–21A](#)). Blunting of the costophrenic angle may occur with as little as 175 mL of fluid on an erect frontal radiograph; smaller amounts of fluid can be detected on a lateral upright or lateral decubitus view but these views are logistically difficult to obtain in the ICU patient. A massive pleural effusion can produce near-complete opacification of the involved hemithorax, accompanied by contralateral mediastinal shift ([Figure 11–21B](#)).

Multiple diagnostic challenges exist when visualizing pleural effusions with a chest radiograph. Atelectasis and lung consolidation may be difficult to distinguish from pleural effusion because they too may obscure the hemidiaphragm. Pleural fluid can accumulate along the pleural fissures and result in a mass-like appearance, or pseudotumor. However, unlike a true mass, a pseudotumor will change in shape and size as the patient is repositioned. Pleural effusions may also be found in a subpulmonary location between the lung base and diaphragm without causing blunting of the lateral costophrenic sulcus.

The chest radiograph will reveal what appears to be an elevated hemidiaphragm, which is actually the displaced pleural-visceral interface simulating a “pseudodiaphragm.” Signs that can help distinguish subpulmonic effusion from diaphragmatic elevation include the fatter shape of the pseudodiaphragm in comparison with a true hemidiaphragm, and increased distance between the gastric bubble and the pseudodiaphragm ([Figure 11–22](#)).

An additional challenge specific to ICU patients is that many radiographs are performed with the patient in the supine position, making the diagnosis of pleural effusion more difficult, particularly with smaller effusions. When a patient is supine, the most dependent regions of the pleural space are the posterior aspects of the bases and the lung apex. Free pleural effusions layer posteriorly, resulting in a homogeneous increased density of the lower involved hemithorax. Fluid also may accumulate at the apex of the thorax, resulting in apical capping.

Given the limitations of chest radiography in visualizing pleural effusions, ultrasound and CT are frequently utilized. Ultrasound imaging is detailed in Chapter 12. Pleural effusions on CT typically appear as sickle-shaped, posterior opacities ([Figure 11–23](#)).

FIGURE 11–22 Separation of the left “hemidiaphragm”(arrows) from the stomach bubble suggesting a subpulmonic pleural effusion.

CT is extremely sensitive in the detection of small effusions, demonstrating loculations, and distinguishing pleural and parenchymal processes. In complicated cases, intravenous contrast administration can help differentiate parenchyma from pleura, as consolidated lung will enhance, whereas pleural processes will not. While the attenuation of

FIGURE 11–23 Large bilateral pleural effusions demonstrated on CT scan.

the effusion cannot help distinguish all transudates from exudates, very high attenuation may suggest the presence of a hemorrhagic or proteinaceous collection.

One typically high-attenuation collection is an empyema. Empyema is defined as pus in the pleural space and warrants additional radiographic considerations. While empyemas may initially appear as free-flowing pleural effusions, they often subsequently develop loculations as they pass through their fibrinopurulent and organizing phases. Loculations appear lenticular in shape with obtuse angles to the chest wall. If a concurrent bronchopleural fistula is present, an air-fluid level can be identified in the pleural space. Air-fluid levels can also be seen in lung abscesses, making the 2 difficult to distinguish on a frontal chest radiograph; CT imaging can better distinguish the 2 given its cross-sectional nature. The visceral and parietal pleura frequently enhance due to increased blood supply to the inflamed pleural surfaces during the organizing phase with resultant uptake of intravenous contrast. The “split pleura” sign results from this enhancement as well as separation of the visceral and parietal pleura. Surrounding edema and a local increase in extrapleural fat are also often seen, suggesting the chronic nature of the empyema (Figure 11–24).

PNEUMOTHORAX

General Considerations

Pneumothorax is a frequent and serious complication in the ICU. Iatrogenic pneumothorax frequently develops as a sequela of invasive diagnostic or therapeutic procedures, or barotrauma from mechanical ventilation. Other etiologies of pneumothorax include chest trauma and complications of pulmonary diseases such as COPD, asthma, interstitial lung disease, and cavitary pneumonia. Recognition of even small pneumothoraces is crucial for the prevention of progressive accumulation of pleural air collections, particularly in patients being maintained on mechanical ventilation.

Radiographic Features

As with fluid in the pleural space, the distribution of a pneumothorax is influenced by gravity, lung elastic

(a)

(b)

FIGURE 11–24 **A.** Air-fluid level in an empyema with a bronchopleural fistula. **B.** Split pleura sign: large empyema (E) with separated, enhanced visceral (V) and parietal (P) pleura as well as thickening of extrapleural fat (F).

recoil, potential adhesions in the pleural space, and the anatomy of the pleural recesses. Radiographically, a pneumothorax is identified by separation of the visceral pleural surface from the chest wall and the absence of pulmonary vessels peripheral to the pleural line. A pneumothorax is typically better seen on expiratory images because of a relative decrease in lung volumes compared with the air in the pleural

space. In the upright patient, air accumulates in the nondependent region of the pleural space, the apex.

Expiratory, upright radiographs are generally unattainable in ICU patients; images are usually obtained in the supine position, altering the radiographic appearance of pneumothorax. In this position, the least dependent regions of the pleural space are the anteromedial and subpulmonary regions. Pleural air in the anteromedial space results in sharp delineation of mediastinal contours, including the superior vena cava, the azygos vein, the heart border, the inferior vena cava, and the left subclavian artery. The accumulation of air in the subpulmonary region results in a hyperlucent upper quadrant of the abdomen, a deep, hyperlucent lateral costophrenic sulcus (“deep sulcus sign”), sharp delineation of the ipsilateral diaphragm, and visualization of the inferior surface of the lung (Figure 11–25). Air can accumulate in the apicolateral pleural space in the supine patient just as in the erect patient, especially when a large pneumothorax is present. In the presence of lower lobe pneumothorax, air can accumulate in the posteromedial pleural recess, resulting in sharp delineation of the posterior mediastinal structures, including the descending aorta and the costovertebral sulcus.

Tension pneumothorax occurs when the pressure of air in the pleural space exceeds ambient

FIGURE 11–25 Large left-sided pneumothorax (red arrows) as a complication of subclavian line placement. Rightward tracheal shift (black arrows) and sharp delineation of the left hemidiaphragm (blue arrow) can be seen.

pressure during the respiratory cycle. With this pressure gradient, air enters the pleural space on inspiration but is prevented from exiting the pleural space during expiration. A tension pneumothorax may result in acute respiratory distress and, if untreated, cardiopulmonary arrest. Radiographic signs include displacement of the mediastinum toward the contralateral thorax, inferior displacement or inversion of the diaphragm, and total lung collapse. Adhesions may prevent mediastinal shift, and lung collapse may not occur in patients with stiff lungs such as those with ARDS.

Bedside ultrasound is a reliable tool for the diagnosis of pneumothorax and is further described in Chapter 12. CT may be particularly useful in the diagnosis of loculated pneumothorax and in guiding appropriate chest tube placement.

Several conditions may be confused with a pneumothorax. Pneumoperitoneum may result in a hyperlucent upper abdomen, mimicking pneumothorax. Skin folds can be confused with apicolateral pneumothorax but should be recognized when they extend outside the bony thorax or are traced bilaterally. Pneumomediastinum may simulate medial pneumothorax; however, pneumomediastinum will often cross the midline and extend into the retroperitoneum.

Imaging The Critically Ill: Bedside Ultrasound

Alfredo Lee Chang, MD; Lewis Ari Eisen, MD and Marjan Rahmanian, MD

KEY POINTS

- 1 Focused critical care ultrasound (CCU) answers specific clinical questions and is an extension of the physical examination.
- 2 Bedside ultrasound can benefit patients by decreasing ionizing radiation exposure and improving patient safety by decreasing the need for transport out of the intensive care unit (ICU).
- 3 Bedside ultrasound is better for ruling in diagnoses than ruling out diagnoses.
- 4 If the diagnosis is unclear after a focused ultrasound, expert consultation or additional imaging is advised.
- 5 Bedside ultrasound is shown to decrease complications and improve success rates for many common critical care procedures.

INTRODUCTION TO BEDSIDE ULTRASOUND

Ultrasound technology was introduced to the medical field in the early 1950s. It was not until 1970s that multiple specialties in medicine adopted ultrasound as a useful diagnostic tool. Slasky et al mentioned the importance of ultrasound in the ICU. He reported a 2-year retrospective study of ultrasound indications in the ICU and found that 64.4% of patients had abnormal findings and 52% of these patients' clinical course and therapy were modified by ultrasonography.¹ Other authors reported similar findings.²⁻⁴

Bedside ultrasonography differs from the ultrasound studies done by consult services (ie, cardiology, radiology, etc). The intensivist uses real-time (image acquisition and interpretation are done at the same time) point-of-care ultrasonography (POC-US) to answer simple clinical questions that will change patient's management. One clear

example of POC-US frequently used by emergency physicians and trauma surgeons is the focused assessment by sonography for trauma (FAST). It has become standard of care and it is fully integrated into advanced trauma life support teaching. For intensivists, POC-US helps diagnose, evaluate response to treatment and guide procedures safely.

In this chapter we will cover the basics of image acquisition and clinical applications of POC-US.

BASICS OF ULTRASONOGRAPHY

Understanding the basic physics of how ultrasound images are generated will help interpreting images and identifying artifacts. The ultrasound frequency ranges within millions of Hertz (MHz). It is generated when electric current is applied to a piezoelectric crystal. These mechanical vibrations are transmitted through tissues; each tissue will have

TABLE 12–1 Important artifacts in ultrasonography.

Artifacts	Mechanism	Description
Acoustic enhancement	Attenuation of sound	Usually seen after an anechoic structure that does not attenuate the ultrasound wave and generates a brighter image than we would expect.
Acoustic shadows	Attenuation of sound	Usually seen after a hyperechoic structure that obliterate the ultrasound wave and creates a dark shadow.
Side lobe artifacts	Propagation	Consist of low-intensity ultrasound beams located outside of the main beam, generating a “sludge” appearance.
Refraction “edge artifact”	Propagation assumption	Seen when ultrasound waves encounter a curved surface at a tangential angle, these waves are scattered and refracted, thus creating a linear shadow.
Refraction “ghosting”	Propagation assumption	Seen when ultrasound waves travel through materials with different acoustic transmission speeds causing a shadow.
Reverberation artifacts	Propagation assumption	Seen when ultrasound waves are refected back and forth at close intervals, eg, A-line and B-lines.

different impedance, generating echoes throughout. The same transducer, then receives and transduces into a grayscale image that is generated at 20 to 40 frames per second. This is perceived as continuous images on the screen. For deeper structures, low-frequency waves such as 1 to 5 MHz are preferred and for superficial structures, high-frequency waves such as 5 to 15 MHz are preferred. By convention, tissues like the liver and kidneys are isoechoic. Bone, stones, and other tissues that reflect more echoes are hyperechoic and fat, fluid, and blood have low impedance generating hypoechoic or anechoic images.

Basic understanding of acoustic artifacts can help with image interpretation; these are described in [Table 12–1](#).

GUIDELINES AND INTERNATIONAL STATEMENTS

Training and Competency

Despite the potential benefit of POC-US, the use of ultrasound is not universal in critical care medicine. Benefits will only be appreciated if the operator is capable of acquiring and interpreting ultrasound images. Multiple international critical care societies had partnered to establish guidelines to provide competency in POC-US.^{5,6} These guidelines are

intended to create a framework toward an universal standard. For those intensivists interested in POC-US, the World Interactive Network Focused on Critical Ultrasound (WINFOCUS) and the American College of Chest Physician (ACCP) have well-developed training programs that consist of basic concepts of ultrasonography, hands-on image acquisition, and interpretation.

Competency for general critical care ultrasound (GCCU) and critical care echocardiography (CCE) are different, CCE competency is described in chapter 95 of this book.

It is a consensus that courses designed to teach GCCU and CCE should be at least 10 hours divided into lectures and didactic image-acquisition training. The numbers of examination to achieve competency is controversial.⁶

The basic requirements needed to achieve competency as per the ACCP allows the operator to foster self-directed learning ([Table 12–2](#).)

INTERNATIONAL EVIDENCE-BASED RECOMMENDATIONS

To date, the only evidence-based recommendation for POC-US is for lung ultrasonography (LUS).⁷ A panel of experts voted for the level of evidence in each condition where lung ultrasonography is used.

TABLE 12–2 American College of Chest physician requirements to achieve critical care ultrasonography competency.

Areas of Study	Required Images for Competency
Lung/pleural study	1. Three pleural effusions of any size 2. Three lung sliding 3. Three alveolar consolidation
Abdominal study	1. Four longitudinal view of the left kidney with splenorenal space 2. Four longitudinal view of the right kidney with hepatorenal recess 3. Four transverse bladder views
Vascular diagnostic study	1. Three right common femoral vein with compression 2. Three left common femoral vein with compression 3. Three right common femoral vein at saphenous intake with compression 4. Three left common femoral vein at saphenous intake with compression 5. Three right superficial femoral vein with compression 6. Three left superficial femoral vein with compression 7. Three right popliteal vein with compression 8. Three left popliteal vein with compression

The level of evidence was classified as following: Level A: high-quality evidence and further research is very unlikely to change the estimated effect or accuracy of evidence. Level B: Moderate quality and further research is likely to have an important impact on estimated effect or accuracy and may change level of evidence. Level C: Low quality of evidence and further research is likely to change the estimated effect or accuracy of evidence (Table 12–3).

Lung Ultrasonography

Ultrasound Probe Selection and Orientation

The preferred probe to evaluate the thorax is a 3.5 to 5 MHz with a small footprint and the cursor pointing cephalad. If more superficial structures of the thorax are being investigated, a 7.5- to 10-MHz linear probe can be used.

The classical views of the chest are in the midclavicular line, midaxillary line, and posterior axillary

or mid scapular line. However, scanning other parts of the chest may be indicated as long as good images are obtained for interpretation.

Clinical Implications and Description of Syndromes

In the hands of an experienced operator, LUS in the critically ill is superior to chest roentgenogram (CXR) and comparable to computerized tomography of the chest (CT-Chest) in several conditions.^{8,9} It is important to understand the air-fluid ratio in the lung to understand and interpret LUS. The air-fluid ratio in pneumothorax (PTX) is pure air, no fluid; normal lung has air and very little fluid, the interstitial syndrome has air with more fluid; alveolar consolidation has little air but a lot of fluid and pleural effusion consists of pure fluid, no air. (Figure 12–1).

The only way to image the lung is in between the ribs (Figure 12–2). The lung has to be centered in the screen and the two rib shadows are seen on the side; this is referred to as the bat sign. The pleural line can be identified as a bright structure. Standard ultrasound probes cannot separate the visceral from the parietal pleura so only one line is seen. In a healthy lung, the pleural surfaces move against each other during the respiratory cycle causing a shimmering line, this is called lung sliding. Lung pulse is referred to the pleural line moving synchronously with each cardiac cycle. A normal aerated lung will show reverberations artifact from ultrasound reflection between the pleural line and the skin surface, these are called A-lines. In the presence of lung sliding, A-lines indicate normally aerated lung. In the absence of lung sliding, A-lines do not necessarily indicate normal lung and pneumothorax could be present.

The Interstitial Syndrome—B-lines represents thickened subpleural interlobular septa and/or ground-glass opacity,¹⁰ either of cardiogenic or non-cardiogenic etiology. They are described as comet-tail artifact and must fulfill all of these requirements: (1) Starts from the pleural surface, (2) moves with lung sliding, (3) erases A-lines (4) reaches the bottom of the screen. If any one of the requirements is not met, it is not a B-line.

B-line artifact can be seen in interstitial syndromes (Table 12–4). A few B-lines in the bases of

Data from Volpicelli G, Elbarbary M, Blaivas M, et al: International evidence-based recommendations for point-of-care lung ultrasound, Intensive Care Med. 2012 Apr;38(4):577-591.

the lung are considered normal but more than three B-lines in a single field should be considered abnormal (Figure 12–3).

Diffuse bilateral B-line pattern with smooth pleura is consistent with cardiogenic interstitial

edema.¹¹ Diffuse bilateral B-line pattern with an irregular pleura is usually seen in adult respiratory distress syndrome. Focal irregular pleura with B-lines can be interpreted as early or atypical pneumonia in an appropriate clinical setting.

Malignancies
Lung infarction
Absorptive atelectasis

The Alveolar Consolidation Syndrome—The alveolar consolidation syndrome refers to any condition that can fill the alveoli with fluid (Table 12–5). About 98.5% of alveolar consolidations reach the pleura, enabling ultrasound examination. In a supine patient, 90% of consolidations can be found in the most dependent area of the thorax.⁸ The tissue-like sign is an echoic pattern, with regular trabeculation reminiscent of an ill-defined liver (Figure 12–4). Ultrasound has a 90% and 98% sensitivity and specificity, respectively.⁸ In alveolar consolidation syndromes 2 types of air bronchograms can be seen, static and dynamic. Dynamic air bronchograms indicate the presence of air moving within the bronchus with each breathing cycle, ruling out absorptive atelectasis. A static air bronchogram indicates obstruction of the bronchus causing absorptive atelectasis.

FIGURE 12–4 Alveolar consolidation syndrome seen in pneumonia. (Image courtesy of Sahar Ahmad, MD).

Pleural Ultrasonography

PTX occurs in 6% of the ICU patients¹² and up to 30% of those can be misdiagnosed on conventional CXR owing to the supine position of the critically ill patient.¹³ The gold standard to diagnose PTX is CT-Chest; this involves transferring the patient with all the risks associated with it. Luckily ultrasound can help us identify PTX by scanning the anterior chest. Once the bat sign is identified, the absence of lung sliding plus a diffuse A-line pattern should prompt us to consider the diagnosis of PTX (Figure 12–5). Lung point indicates the point where the lung is touching the chest wall and moves with each respiratory cycle, this is 100% specific for PTX. The sensitivity of lung point for PTX detection is not 100% since this is usually absent in large PTX. It is important to mention that the presence of lung pulse or B-lines rule out PTX in 100% of the cases.

Another phenomenon described in left side PTX is the flickering image in the parasternal long axis view of the heart. The heart is seen in mid-diastole and disappears in midsystole. This is explained by the transient interposition of air between the chest wall and the heart, making it hard to visualize when it is empty and not in contact with the chest wall. This is called heart point (Figure 12–6).¹⁴

Pleural effusion is a very common finding in ICU patients.¹⁵ It collects in dependent areas unless

FIGURE 12–5 This image shows pneumothorax, note the absence of lung sliding that is represented as stratosphere sign (arrows) and sliding lung represented by seashore sign (in between arrows) in M-mode. Intermittent seashore and stratosphere sign is seen in the lung point.

Khan R, Rahmanian M, Kaufman M, et al: The Heart Point Sign: An Ultrasonographic Confirmation Of Pneumothorax, 2013.)

loculated. By using the signs described below, ultrasound can achieve a sensitivity and specificity of 93%.⁹

A big pleural effusion is easily identified and must be distinguished from ascites. Using simple static and dynamic signs, we can tell them apart. The lung can be identified as a consolidated mass usually with air bronchograms, floating in fluid. This is called the jellyfish sign. The diaphragm should be identified above the liver and the spleen, if there is no jellyfish sign in a big effusion; the structure is likely to be the liver (or spleen), not the lung (Figure 12–7).

(a)

(b)

FIGURE 12–7 Image A represents a pleural effusion; look at the similarities with ascites in Image B. It is important to determine static and dynamic signs to differentiate between pleural effusions from ascites.

Ultrasound can also help identify the nature of the pleural effusion. A complex anechoic or hypoechoic space with septations most likely represents an exudative effusion ([Figure 12–8](#)).¹⁶ Sometimes this effusion can be seen as a “thick effusion” meaning a tissue-like echogenicity but with particles swirling around. This is called the plankton sign, which is seen in empyema and hemothorax ([Figure 12–9](#)).

Diaphragm Evaluation

This structure usually is easily visualized above the liver or spleen. There have been studies examining diaphragm thickness and strength. It is well

FIGURE 12–8 Septated pleural effusion usually seen in an exudative effusion. These strands resembling spider webs are floating in the pleural effusion.

known that thinning of the diaphragm starts within 18 hours of muscle inactivity.¹⁷ This was demonstrated by ultrasonography in 7 patients measuring the diaphragm using the 7.5- to 10-MHz linear probe placed in the midaxillary line to measure the apposition area ([Figure 12–10](#)).¹⁸ The utility of this should be further studied. Another promising use for ultrasonography of the diaphragm includes evaluation of its excursion during weaning from mechanical ventilation. Kim et al found that in patients with diaphragm dysfunction, defined when diaphragm excursion was less than 10 mm, weaning

FIGURE 12–9 Plankton sign is usually seen when debris exist within the pleural effusion; it can be pus or blood (see arrow).

FIGURE 12–10 Diaphragm thickness (in between arrows). Image acquired in the apportion area.

failure rate was higher when compared to patients with diaphragm excursion of more than 10 mm.¹⁹

Critical Care Echocardiography

Echocardiography, either transthoracic echocardiography or transesophageal is a very helpful tool in the critically ill patient. This will be discussed in detail in Chapter 94 of this book.

Abdominal Ultrasonography

Ultrasound Probe Selection and Orientation

The preferred ultrasound probe to evaluate the abdominal area will be a 3.5 to 5 MHz with a small footprint with the cursor pointing cephalad.

Clinical Implications of Abdominal Ultrasonography and Recognition of Important Structures

The intensivist should be capable of performing and interpreting simple abdominal ultrasonography. Detailed ultrasound examination of the abdominal organs is out of the scope of this book. It is our practice to perform abdominal POC-US paying attention to liver, spleen, kidney, bladder, gallbladder, aorta, and intestines.

Recognition of the Peritoneal Space

The parietal and visceral layers are in touch with each other and slide with each respiratory cycle; this is called gut sliding.

It is imperative to look for free fluid in an unstable patient. We have found FAST very useful in different situations outside the classic trauma population.

The peritoneal fluid can range from anechoic to hyperechoic, depending on the etiology. Transudates will have an anechoic nature, an hemoperitoneum can be visualized depending on the amount and time elapsed since bleeding started; it could be mildly hyperechoic with plankton sign or more hyperechoic if the blood had already organized. An exudative effusion causing infectious peritonitis could have septations. Ultrasound is more sensitive for detecting septations than CT scan.

Pneumoperitoneum (Figure 12–11) can be detected with ultrasound using the same concepts we have learned in pneumothorax. There are a couple of signs that will help us identify this condition: (a) Gut sliding: as described above, can rule out pneumoperitoneum. (b) Splachnogram: it is when an abdominal organ can be seen with ultrasound, thus, ruling out pneumoperitoneum between the probe and the organ.

The presence of these 2 signs can rule out pneumoperitoneum accurately.

Kidney and Bladder

The probe should be oriented with the pointer cephalad and placed in the posterior axillary line under the costal border; once the liver or the spleen is identified, the kidney is easier to find.

FIGURE 12–11 Pneumoperitoneum detected through ultrasonography. Please note the reverberation artifact resembling the lung A-line. There is no splachnogram. Used with permission from Sahar Ahmad, MD.

FIGURE 12-12 Acute hydronephrosis of the right kidney.

Acute renal failure (ARF) is frequently encountered in the critically ill patient. The etiologies are classified into prerenal, renal, and postrenal. Ultrasound is useful as an initial screening tool.

The evaluation of the renal parenchyma by ultrasound is complex but we can briefly mention some concepts. ARF can be differentiated from chronic renal failure (CRF) because in the latter small kidneys with thin parenchyma and irregular borders are seen. Corticomedullary dedifferentiation can be seen in multiple conditions. In acute medical renal disease the renal parenchyma becomes more echogenic. The renal pelvises are well visualized under ultrasound. Chronic dilatation causes rounded renal calyces and the acute dilatation causes flatter renal calyces ([Figure 12-12](#)).

The bladder is very well visualized in the suprapubic area with the probe held transversely. A full bladder can be identified as an anechoic structure, if the patient has an urinary catheter, this can be easily visualized ([Figure 12-13](#)). Furthermore, ultrasound of the bladder can be used to check for urinary retention without using a catheter.

Ultrasound of the Abdominal Aorta

The aorta is a very important structure to evaluate in an unstable patient and in someone who has been complaining of abdominal or flank pain. Abdominal aortic aneurysm (AAA) rupture has a high mortality rate (around 50%) and ultrasound has been shown to be a reliable method of evaluating AAA.

FIGURE 12-13 Urinary catheter balloon inside the bladder.

The thoracic aorta is better evaluated with a transesophageal echocardiogram or contrast computerized tomography. The abdominal aorta is easily visualized by transabdominal ultrasound.

The aorta is evaluated with the ultrasound probe placed in the midline of the abdomen and the cursor pointing toward the patient's right when a transverse view is desired and pointing toward the head when a longitudinal view is desired. The aorta should be studied from the epigastrium until the bifurcation to the iliac arteries ([Figure 12-14](#)). A diameter greater than 3 cm is considered aneurysmal. Ultrasound is not very sensitive to evaluate for aortic dissections but if a false lumen is seen, it is highly specific for such disease.

Gastrointestinal Tract

The esophagus is usually very difficult to visualize under ultrasound. It becomes visible and feasible for ultrasound assessment once it enters the abdomen to join the stomach. Ultrasound evaluation of the abdominal part of the gastrointestinal (GI) tract is very useful in the critically ill patient.

One observational study showed the utility of identifying gastric contents with ultrasound and performing suctioning prior to emergent endotracheal intubation.²⁰ It is thought that this can potentially decrease the chances of aspiration during intubation. The use of ultrasound had also been described for confirmation of

(a)

(b)

FIGURE 12–14 Image A shows a normal abdominal aorta with the inferior vena cava located on the left. Image B shows a dissection flap (arrow) inside the abdominal aorta.

nasogastric tube and Sengstaken-Blakemore tube positioning.^{21–23}

When evaluating the GI tract, it is important to observe the wall thickness that usually ranges around 2 to 4 mm. It is also very important to observe for gut sliding and peristalsis; the latter are permanent dynamic crawling contractions seen from the antrum of the stomach until the terminal ileus. The presence of peristalsis is rare in a true surgical abdomen.

Liver, Gallbladder, and Spleen

The liver is rarely a target in a critically ill patient despite its size. It acts as an acoustic window to access the heart, Morrison pouch and inferior vena cava analysis. However in some occasions, gross abnormalities can arise such as the following: (a) Liver abscess: yields a round heterogenous hypoechoic image within the regular hepatic echotexture easily identifiable. A highly hyperechoic image can represent microbial gas. (b) Portal gas: as a result of mesenteric infarction. Hyperechoic images disseminated within the liver parenchyma mainly in the periphery and resembling alveolar consolidation with air bronchograms. (c) Liver cirrhosis: yields a coarse and nodular pattern with atrophy ([Figure 12–15](#)). (d) Hepatic tumors: Metastatic tumors are usually multiple iso- or hypoechoic masses. However an echoic heterogeneous mass within a cirrhotic parenchyma suggests hepatoma.

A simple biliary cyst is usually described as a simple anechoic structure with thin walls ([Figure 12–16](#)).

The gallbladder can be viewed during ultrasound of the right upper quadrant. The following findings are suggestive of acute cholecystitis: (1) Enlarged gallbladder over 90 mm in long axis and over 50 mm in short axis. (2) Thickening of the wall greater than 3 mm. (3) Sludge or stones seen within gallbladder. (4) Perivesicular fluid collection. (5) Murphy sign. The sensitivity drops if all the criteria are used but specificity increases.

Cardiogenic or noncardiogenic gallbladder wall edema can confound the diagnosis of acute cholecystitis.

FIGURE 12–15 A small liver compatible with liver cirrhosis, the similarity with a consolidated lung can confuse the nonexperienced operator between ascites and pleural effusion.

FIGURE 12-16 Liver tumor with metastasis (arrows).

Spleen analysis in the critically ill is seldom revealing. It acts as an acoustic window for different organs and also to localize the diaphragm while planning for thoracentesis. In a trauma patient, splenic laceration can be detected and in rare instances a splenic abscess is seen.

Deep Venous Thrombosis Assessment

Ultrasound Probe Selection and Orientation

The high-frequency 7.5 to 10 MHz linear probe is preferred in our institution with the cursor pointing toward the right of the patient.

Introduction of Venous Ultrasonography of the Lower Extremities

Deep vein thrombosis (DVT) and pulmonary embolism (PE) are a spectrum of the same disease. In a rapidly decompensating patient, either in the hospital ward or in the ICU, DVT and PE should always be in the differential diagnosis. Blood test such as d-dimer is nonspecific in the hospitalized patient. Ultrasound of the lower extremities can successfully diagnose DVT. When done by a trained intensivist, the sensitivity and specificity are very similar to examinations done by the radiology technician and interpreted by a radiologist.²⁴ A DVT can be found in the upper and lower extremities. We will focus on lower extremity anatomy here.

The patient should be positioned in the decubitus position with the leg slightly flexed and externally rotated (**Figure 12-17**). The leg should be examined by performing gentle and firm compression, enough to collapse (**Figure 12-18**) the vein but not the artery. A vein with DVT will not collapse. (**Figures 12-19** and **12-20**).

The operator should be familiar with the lower extremity venous anatomy (see **Figure 12-20**). The ultrasound probe should be placed at the level of the inguinal ligament to localize the femoral vein, which is medial to the femoral artery. Once this is identified, a compression movement is performed to check for collapsibility, a collapsible vein rules out DVT. A noncollapsible vein, rules in DVT. Color

(b)

FIGURE 12–19 Femoral vein in a patient with suspected deep venous thrombosis. Image A without compression and Image B showing the vein is not collapsible.

FIGURE 12–20 Important veins of the lower extremity, it is important to be familiar with the anatomy in order to interpret where the DVT is located. Dark blue: Deep vein. Light Blue: superficial vein.

Doppler can be used but will increase study time without adding much information. Unfortunately, the external iliac veins are not visualized fully but can be partially visualized if the probe is tilted and pointing the ultrasound beam “under” the inguinal ligament. Once the common femoral vein (CFV) is studied, the drainage of the greater saphenous vein can be seen medially. A couple of centimeters below, the CFV bifurcates in deep femoral vein and superficial femoral vein (SFV). It is important to recall that the SFV is still part of the deep venous system. Compression should be done every 2 to 3 cm while identifying the perforating branches until the vein enters the adductor canal if visibility allows. The popliteal vein should also be studied with the leg bent and the sole of the foot on the bed (see Figure 12–17). The popliteal vein should be located superficially to

the artery. Again, firm pressure is applied to evaluate compressibility.

How can we integrate these findings in our clinical assessment? A hypoxic patient with positive DVT and bilateral A-line pattern in the lung, PE should be suspected. Furthermore, a quick echocardiogram should be done and if there are signs of right ventricle overload, submassive or massive PE is highly suspected.

Optic Nerve Ultrasonography

Probe Selection and Orientation

It is usually performed with the high-frequency 7.5 to 10 MHz linear probe and it is placed over the eyelid. The optic nerve sheath (ONS) will be identified and then measured (Figure 12–21).

FIGURE 12–21 Optic nerve sheath measurement. In this particular case, it was not enlarged.

Competency Requirements

It is estimated that 10 studies could be sufficient in experienced US operators and 25 studies for inexperienced US operators to achieve competency.²⁵

Clinical Implications

The gold standard for detection of an elevated intracranial pressure (ICP) is invasive measurement. These methods can lead to complications such as infection or bleeding. Other methods are described but we found US measurement of the optic nerve sheath diameter (ONSD) an excellent screening test for elevated ICP.

When ONSD is compared to the gold standard, a pooled analysis using cutoff value range from 5.2 to 5.9 mm showed a sensitivity and specificity of 74% to 95% and 74% to 100%, respectively.²⁶ In another meta-analysis²⁷ the pooled sensitivity and specificity was 90% and 85%, respectively. One study using 5 mm as a cutoff²⁸ yielded 100% and 95% sensitivity and specificity, respectively.

PROCEDURAL GUIDANCE

Several procedures can be done in the intensive care unit (Table 12–6). These procedures will be described in details in subsequent chapters. When possible, the dynamic technique, which involves direct visualization of the needle tip, is highly

TABLE 12–6 Procedures done under ultrasound guidance in critical care.

- Paracentesis
- Thoracentesis
- Pericardiocentesis
- Central venous line placement
- Arterial line placement
- Transthoracic-guided biopsy, for microbiological sampling or malignancy
- Lung abscess drainage
- Liver or spleen abscess drainage
- Lumbar puncture
- Peritoneal collection drainage
- Pacemaker placement
- Percutaneous gallbladder drainage
- Percutaneous bladder drainage

recommended for nearly all procedures. Continuous vision of the needle tip will ensure low complication rates.

CONCLUSION

POC-US is a helpful noninvasive tool that benefits the critically ill patient. It is easy to perform and learn but requires practice to master. POC-US should be incorporated in the skills of every intensivist.

Patient Safety in the ICU

Jason Adelman, MD, MS

KEY POINTS

- 1 The intensive care unit (ICU) is particularly prone to medical errors as patients are very ill and require continuous monitoring.
- 2 A patient safety program that drives improvement for critical care patients can be categorized into 4 general domains: (1) ensuring compliance with patient safety regulations; (2) responding to adverse events by performing root cause analyses and implementing targeted corrective actions; (3) applying evidence-based risk reduction strategies that are not required by regulations, but are considered best practices; and (4) implementing strategies to meet and exceed patient safety metrics that are publicly reported or tied to pay-for-performance programs.
- 3 To prevent wrong patient errors, the Joint Commission requires the use of at least 2 patient identifiers when administering medications and blood products, when collecting laboratory specimens and taking imaging tests, and when providing any type of treatment.
- 4 The majority of adverse events are never reported and therefore cannot be addressed.
- 5 When a serious adverse event happens to a critical care patient, a systematic investigation of the event, called a root cause analysis, should be completed by an interdisciplinary team that has expertise in the areas involved in the event.
- 6 According to the Just Culture concept, the major focus of an adverse event investigation should be on potential system failures that led to the error as opposed to simply attributing blame to the providers involved in the error.
- 7 Team training is a well-established approach for preventing errors in high-risk industries such as the military and the airline industry, and is now being applied to the medical industry.
- 8 Simulation is a promising new strategy for improving patient safety. Similar to flight simulators used by the airline industry, health care simulators allow providers to learn a procedure or protocol using high-tech mannequins instead of live patients.
- 9 Pay-for-performance is a new approach for driving improvement in medical care by using financial incentives to reward hospitals that perform well on preestablished safety and quality measures.
- 10 Those who want to lead in patient safety should innovate new approaches for preventing errors, and study these approaches using rigorous research methodology.

PATIENT SAFETY IN THE INTENSIVE CARE UNIT

The modern patient safety movement began with the release of the 1999 Institute of Medicine (IOM) report “To Err Is Human,” which estimated that up to 98,000 patients die each year from medical errors. This high number of deaths exceeded the number attributed to the eighth leading cause of death at the time, and helped refocus the health care community on the importance of patient safety. The ICU is particularly prone to medical errors as patients are very ill and require continuous monitoring. The care of ICU patients can be complex, involving multiple consultants and many medications, where life-and-death decisions often need to be made quickly. A 2006 international study of 205 ICUs found an average of 38.8 events that compromised patient safety per every 100 patient critical care days, highlighting the need for risk reduction and complication avoidance strategies in ICUs.

The Four Domains of a Patient Safety Program

A patient safety program that drives improvement for critical care patients can be categorized into 4 general domains (Figure 13–1): (1) ensuring compliance with patient safety regulations (eg, The Joint Commission National Patient Safety Goals [NPSGs]); (2) responding to adverse events by performing root cause analyses and implementing targeted corrective actions (eg, delayed response to a ventilator alarm); (3) applying evidence-based risk reduction strategies that are not required by regulations, but are considered best practices (eg, checklists); and (4) implementing strategies to meet and exceed patient safety metrics that are publicly reported or tied to pay-for-performance programs (eg, hospital-associated infections reported on public report cards). Hospitals that are leaders in patient safety excel in each of these 4 domains, and also contribute to the science of patient safety by developing new strategies for preventing errors, conducting research, and publishing their findings.

Patient Safety Regulations

The Joint Commission NPSGs are the predominant patient safety regulations that guide hospitals’

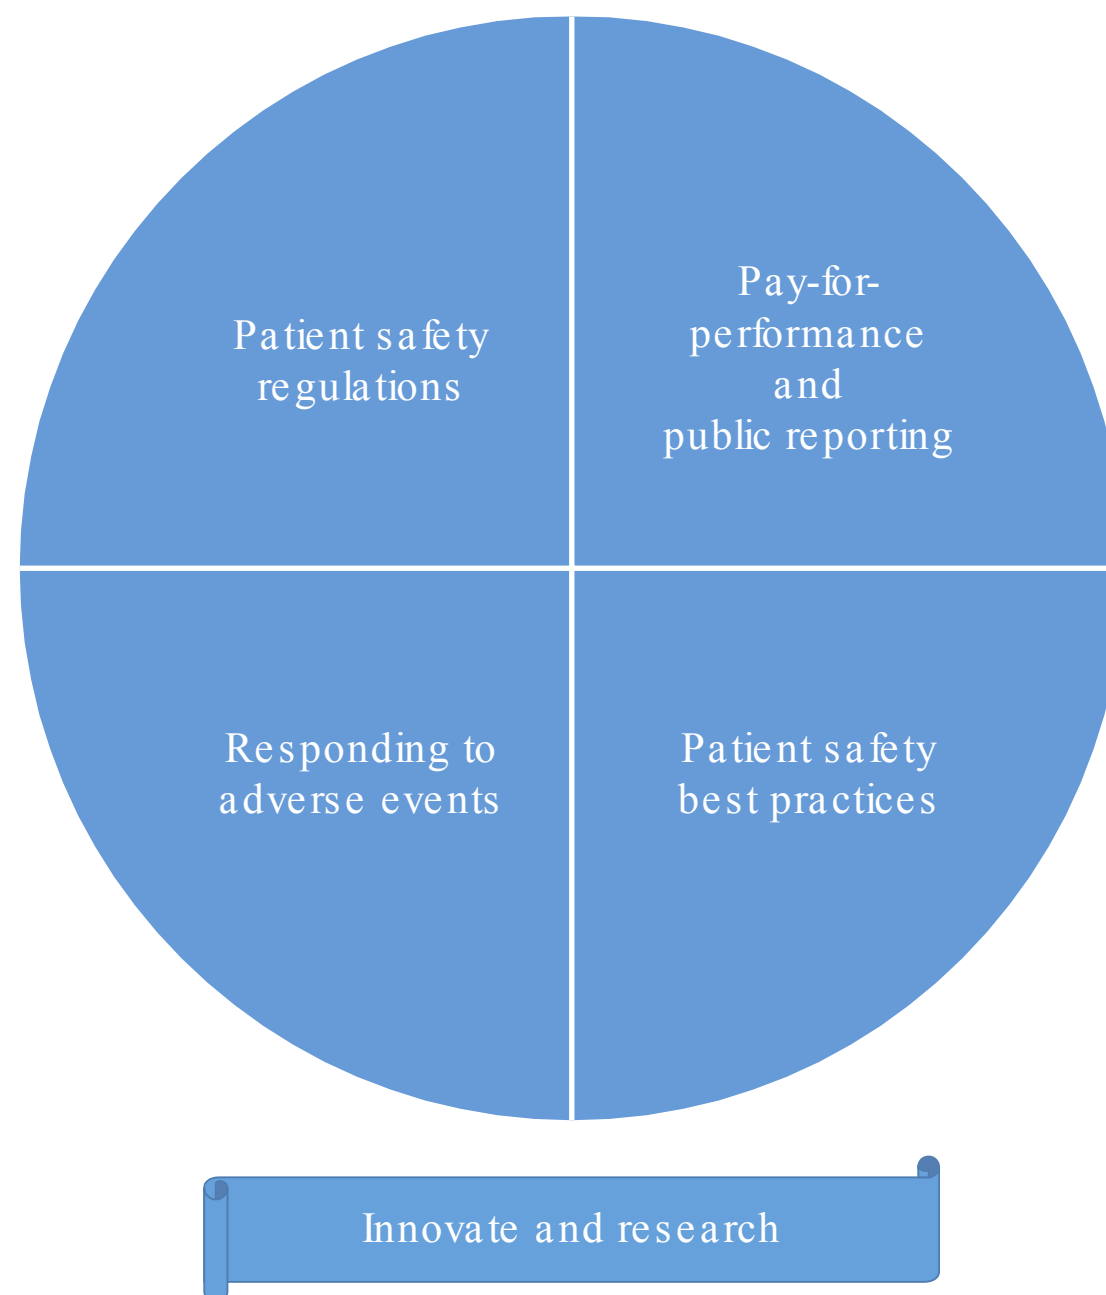

FIGURE 13–1 Four domains of a patient safety program.

medical error reduction strategies. Established in 2002, the NPSGs require organizations to address specific areas of concern in regard to patient safety. Many of these goals target important patient safety issues in critical care units including proper patient identification, timely response to critical tests, and appropriate use of clinical alarms. Table 13–1 has a complete list of the 2016 Joint Commission NPSGs.

Patient Identification

Wrong patient errors occur in virtually all stages of diagnosis and treatment. On critical care units, patients are often in close proximity, elderly and encumbered with tubes and cannulas. Under these conditions patients can look alike and be confused with one another. To prevent wrong patient errors, the Joint Commission requires the use of at least 2 patient identifiers when administering medications and blood products, when collecting laboratory specimens and taking imaging tests, and when providing any type of treatment.

Critical Test Results

Critical test results that fall significantly outside the normal range and indicate potentially

TABLE 13–1 2016 Joint commission patient safety goals.

Identify patients correctly	<ul style="list-style-type: none"> • Use at least 2 ways to identify patients. For example, use the patient's name and date of birth. This is done to make sure that each patient gets the correct medicine and treatment. • Make sure that the correct patient gets the correct blood when they get a blood transfusion.
Improve staff communication	<ul style="list-style-type: none"> • Get important test results to the right staff person on time.
Use medicines safely	<ul style="list-style-type: none"> • Before a procedure, label medicines that are not labeled. For example, medicines in syringes, cups, and basins. Do this in the area where medicines and supplies are set up. • Take extra care with patients who take medicines to thin their blood. • Record and pass along correct information about a patient's medicines. Find out what medicines the patient is taking. Compare those medicines to new medicines given to the patient. Make sure the patient knows which medicines to take when they are at home. Tell the patient it is important to bring their up-to-date list of medicines every time they visit a doctor.
Use alarms safely	<ul style="list-style-type: none"> • Make improvements to ensure that alarms on medical equipment are heard and responded to on time.
Prevent infection	<ul style="list-style-type: none"> • Use the hand cleaning guidelines from the Centers for Disease Control and Prevention or the World Health Organization. Set goals for improving hand cleaning. Use the goals to improve hand cleaning. • Use proven guidelines to prevent infections that are difficult to treat. • Use proven guidelines to prevent infection of the blood from central lines. • Use proven guidelines to prevent infection after surgery. • Use proven guidelines to prevent infections of the urinary tract that are caused by catheters.
Identify patient safety risks	<ul style="list-style-type: none"> • Find out which patients are most likely to try to commit suicide.
Prevent mistakes in surgery	<ul style="list-style-type: none"> • Make sure that the correct surgery is done on the correct patient and at the correct place on the patient's body. • Mark the correct place on the patient's body where the surgery is to be done. • Pause before the surgery to make sure that a mistake is not being made.

life-threatening conditions are common in intensive care patients. The Joint Commission requires these critical test results be reported within reasonable time frames that are established by the hospital. The intent is for patients to receive appropriate treatment as soon as possible. The Joint Commission also requires that procedures are put in place for tracking these reporting times, and that performance improvement programs are used when reporting times are not within acceptable time frames.

Clinical Alarms

A newly added Joint Commission regulation addresses the safety of improperly managed clinical alarm systems, which are an important part of the care and monitoring of critically ill patients. Clinical alarm systems are intended to alert caregivers of potential patient emergencies, but when improperly configured they can compromise patient safety. Critical care units have numerous clinical alarms,

and the resulting noise and visual warnings can desensitize staff and cause them to miss or ignore these alarms. In some instances critical care staff will disable alarms or set alarm limits to inappropriate thresholds to decrease distractions. This new Joint Commission regulation requires that leaders establish alarm system safety as a hospital priority, establish policies addressing critical issues in alarm management (Table 13–2), and educate staff about the proper operation of alarm systems for which they are responsible.

Failure Mode and Effects Analysis

In addition to the NPSGs, the Joint Commission requires hospitals to perform yearly proactive risk assessments of a high-risk process called a Failure Mode and Effects Analysis (FMEA). When doing an FMEA, an interdisciplinary team of experts create a detailed flow diagram of the high-risk process being evaluated. After this is completed, each step of the

TABLE 13–2 Critical issues in alarm management.

- Establish clinically appropriate settings for alarm signals and who has the authority to set or change alarm parameters.
- Determine when alarm signals can be disabled and who has the authority to set alarm parameters to “off.”
- Develop a system for monitoring and responding to alarm signals.
- Create a process for checking individual alarm signals for accurate settings, proper operation, and detectability.

process is assigned 3 scores: (1) the risk of failure (1-10, with 10 representing the highest risk of failure); (2) the likelihood that the failure will be intercepted before reaching the patient (1-10, with 10 representing the least likelihood of interception); (3) the risk that the failure will cause harm (1-10, with 10 representing the highest risk for harm). The product of these three numbers is the hazard score. The steps in the workflow with the highest hazard score should be the first to be evaluated for performance improvement. In a critical care setting, some high-risk practices that may benefit from an FMEA include responding to clinical alarms, preventing hospital-acquired infections from catheters and central lines, and handoffs between clinicians.

State Regulations

Many states also issue patient safety regulations. Often these regulations pertain to the reporting of adverse events. For example, New York State requires serious adverse events to be reported along with a detailed analysis of what happened and proposed corrective actions. In Pennsylvania, all errors are reported, ranging from near-miss errors that do not cause harm to the most serious errors that lead to death. Other examples of state regulations concern surgical safety, sepsis, and perinatal safety. State regulations that address patient safety continue to evolve, requiring hospital leadership to pay close attention to new state-led initiatives aimed at preventing medical errors.

Responding to Adverse Events

While patient safety regulations address hazards that are believed to be universal in health care

(eg, requiring confirmation of patient identification prior to administering medications), investigating adverse events and implementing corrective actions are opportunities to address issues that may be organization specific. When a serious adverse event happens to a critical care patient, a systematic investigation of the event, called a root cause analysis, should be completed by an interdisciplinary team that has expertise in the areas involved in the event. After a detailed analysis, corrective actions aimed at preventing similar events should be implemented, which can involve rethinking a poorly functioning workflow, purchasing new technology, updating a policy, and/or reeducating staff.

Reporting Adverse Events

Unfortunately, the majority of adverse events are never reported and therefore cannot be addressed. A 2011 study by Classen et al found that among 393 adverse events detected by various mechanisms, only 4 (1%) were identified through voluntary reporting. Several strategies are being implemented to increase the reporting of adverse events. For example, many institutions are moving to electronic adverse event reporting systems that make reporting easier. These systems allow for the reporting of incidents that cause harm (eg, a patient who falls and fractures a hip), near-miss errors that do not cause harm but still provide information about hidden hazards (eg, a patient who trips over a loose wire but catches himself before falling), and unsafe conditions which can potentially lead to adverse events (eg, a loose wire). Reports of incidents, near misses, and unsafe conditions are collectively called “patient safety work product.”

Just Culture

In addition to implementing electronic reporting systems, some hospitals are embracing a concept called Just Culture. According to the Just Culture concept, the major focus of an adverse event investigation should be on potential system failures that led to the error as opposed to simply attributing blame to the providers involved in the error. The need to focus on system failures was highlighted in the IOM report “To Err Is Human” (Figure 13–2), and has become an important staple of modern patient safety programs. Based on this IOM report, a hospital that

Why Do Errors Happen?

“The common initial reaction when an error occurs is to find and blame someone. However, even apparently single events or errors are due most often to the convergence of multiple contributing factors. Blaming an individual does not change these factors and the same error is likely to recur. Preventing errors and improving safety for patients require a systems approach in order to modify the conditions that contribute to errors. People working in health care are among the most educated and dedicated workforce in any industry. The problem is not bad people; the problem is that the system needs to be made safer.”

FIGURE 13–2 Excerpt from the Institute of Medicine Report “To Err Is Human”.

implements Just Culture policies can expect to see an increase in reporting of adverse events as providers come to believe that leadership is committed to improving systems instead of punishing human errors.

Patient Safety Organizations

To optimize lessons learned from adverse events, the federal government enacted the Patient Safety and Quality Improvement Act of 2005 which authorized the creation of patient safety organizations (PSOs) to collect and analyze patient safety work product from health care facilities, and provide feedback and assistance to effectively minimize patient risk. The Patient Safety and Quality Improvement Act also provides federal protections that prohibit the use of patient safety work product in criminal, civil, or disciplinary proceedings in order to encourage providers to report medical errors without fear of repercussions and lawsuits. In addition, the federal Agency for Healthcare Quality and Research (AHRQ) produced a set of common definitions and reporting formats, known as “common formats,” which allow health care facilities to exchange data with PSOs in a standardized manner. PSOs, in turn, transmit deidentified patient safety work product to the national network of patient safety databases (NPSD), which is maintained by AHRQ. The NPSD has been aggregating patient safety data from across the United States, analyzing the data, and eventually will make recommendations for improving patient safety (Figure 13–3).

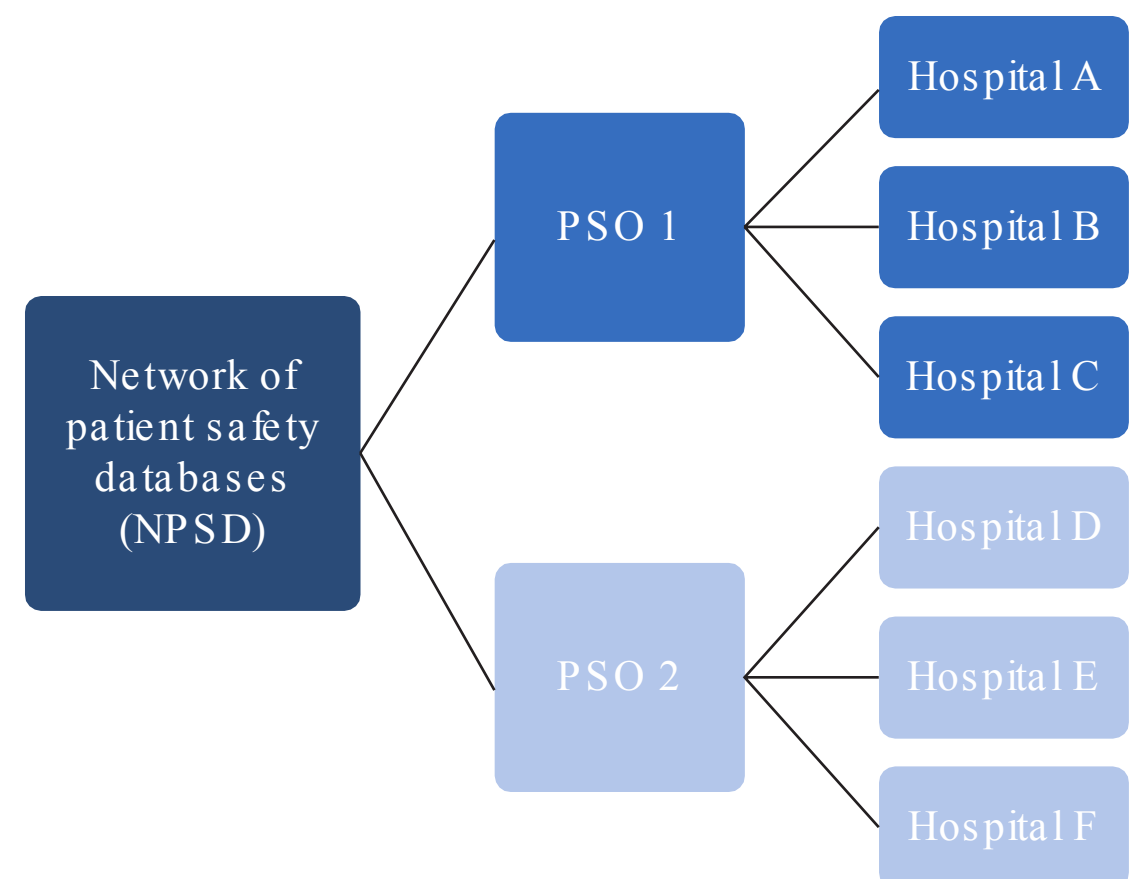

FIGURE 13–3 The network of patient safety databases.

Patient Safety Best Practices

There are many approaches to improving patient safety that are not required by regulation, and not implemented as a direct response to an adverse event. They are good ideas, with strong evidence to support their effectiveness in preventing errors and avoiding complications. Many of these best practices are appropriate in a critical care setting.

Teamwork

Team training is a well-established approach for preventing errors in high-risk industries such as the military and the airline industry, and is now being applied to the medical industry. The underlying theory behind medical team training is that highly trained individuals (eg, physicians, nurses, and technicians) acting together as a cohesive team are more effective and in the best interest of their patients. This includes strong leadership, where the team leader articulates clear goals and makes decisions using input from team members. Effective team work also requires clear communication with briefs and debriefs before and after procedures and complex patient encounters, and ad hoc huddles when unexpected urgent situations arise. It is important that team members “cross-check” each other, offering assistance when needed, and that team members are respectful of each other, so that all team members feel comfortable speaking up.

AHRQ collaborated with the United States Department of Defense to develop a team training program called Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS), which is specifically designed for the medical industry. Many hospitals are now using the AHRQ TeamSTEPPS program to teach the principles of medical team work, with a focus on 4 core competencies: team leadership, situation monitoring, mutual support, and communication.

In one study, an academic medical center reported on the implementation of the TeamSTEPPS program in their pediatric and surgical ICUs, where all pediatric ICU (PICU), surgical ICU (SICU), and respiratory therapy staff received TeamSTEPPS training. The staff felt the implementation was effective and improved teamwork on the unit and objective patient safety measures significantly improved after the TeamSTEPPS program was implemented. Another study examined the relationship between the level of self-identified teamwork and their mortality rates in 17 ICUs. This study found that the units with lower mortality rates had teams with a deeper understanding of how well their teams functioned, were more trusting of other team members, and perceived themselves as more organized when compared to the units with the higher mortality rates.

Simulation

Simulation is a promising new strategy for improving patient safety. Similar to flight simulators used by the airline industry, health care simulators allow providers to learn a procedure or protocol using high-tech mannequins instead of live patients. The old adage, “see one, do one, teach one” is being replaced by continuous practice in a simulation laboratory. Simulation allows providers to learn new technical skills, practice their responsiveness to high-stress clinical emergencies, and practice working as a team. It is being incorporated into medical school curricula, as well as the continuing education classes of nurses, residents, and attending physicians.

Health care simulation is usually conducted in replicate clinical settings with the same equipment used to treat real patients. It is common for simulation centers to have mock inpatient rooms, emergency bays, and operating suites, each equipped with sophisticated video equipment that captures

multiple angles. Outside the simulation room, often behind a one-way mirror, is a trained technician controlling the faux clinical scenario by manipulating the simulated patient’s vital signs, clinical alarms, and even their verbal responses through a microphone.

The most important part of health care simulation is the debriefing which occurs once the simulated clinical scenario is completed. A video of the simulation is played back, and all participants review their actions with a trained specialist who facilitates the conversation, making sure to highlight what went right and where there are potential areas for improvement. In the ICU, simulation is an ideal tool for teaching residents, fellows, and nurses many aspects of critical care medicine, ranging from the technical skills of placing a central catheter with ultrasound guidance to the essential cultural skill of working effectively together as a team.

Critical Care Staffing and Telemedicine

Patients in critical care units often have life-threatening illnesses which require complicated care plans, rapid decision making, close monitoring, and constant support from highly trained doctors and nurses who specialize in caring for the sickest of patients. Several studies have demonstrated improved outcomes when these patients are cared for in closed units, and when their care is supervised by critical care attending physicians. The Leapfrog Group, which is a consortium of Fortune 500 companies and other large health care purchasers that work together to drive improvements in patient safety, have made appropriate ICU staffing a major pillar in their patient safety program. To meet the Leapfrog Group’s standard on ICU staffing, a hospital must (1) have an intensivist present during daytime hours and provide clinical care exclusively in the ICU, (2) ensure that the intensivists return pages at least 95% of the time when they are not present on site, and (3) arrange for a Fundamental Critical Care Support (FCCS) certified physician or physician extender to reach ICU patients within 5 minutes of being called or paged. When an intensivist is not available on site, it is acceptable if they are available via telemedicine.

The telemedicine model was initially envisioned as a tool for providing specialty medical expertise to rural communities that do not have ready access to

tertiary care; today it is used by critical care medicine as a means of expanding the geographic range of critical care physicians. The critical care physician is often physically located in a room offsite, with access to patient monitors and electronic health records. He or she remotely keeps a watchful eye on the vital signs, laboratory results, and overall well-being of dozens of critically ill patients, sometimes from several different units across a health system. The critical care physician has direct communication with the local ICU team, and is available to them 24 hours a day, 7 days a week.

Pay-for-Performance and Public Reporting

Pay-for-performance is a new approach for driving improvement in medical care by using financial incentives to reward hospitals that perform well on preestablished safety and quality measures. The broad categories of measures used by these programs include surveys of patients' experiences and timeliness and effectiveness of care, as well as readmissions, complications, and deaths. For example, the Center for Medicare and Medicaid Services (CMS) has implemented the 2014 Hospital Value-Based Purchasing (Hospital VBP) Program which adjusts hospitals' payments based on their performance on several safety and quality metrics, some of which are directly affected by the care patients receive in ICUs (eg, pneumonia 30-day mortality rate).

In addition to financial incentives, safety and quality measures are used in publicly displayed hospital report cards that inform patients of each hospital's strengths and weaknesses (eg, Medicare's Hospital Compare website hospitalcompare.gov), thus motivating hospitals to implement programs for improving their performance on these measures and ultimately improving patient safety. Many of the quality and safety measures used in these programs are collected in the ICUs (eg, infection control surveillance data reported for both central line-associated bloodstream infections [CLABSI] and catheter-associated urinary tract infections historically have been collected exclusively from ICUs).

Pneumonia 30-Day Mortality Rate

In the United States, pneumonia results in more than a million admissions each year, and is the second

leading cause of hospitalization among patients over 65 years. As a result, pneumonia has been a focus of quality improvement programs for a decade. The CMS has attempted to accelerate the improvement in the care of patients with pneumonia by publically reporting the 30-day mortality rate for pneumonia patients on Hospital Compare, and have included this same metric in their pay-for-performance value-based purchasing program.

Central Line-Associated Bloodstream Infections

An estimated 80,000 CLABSI occur in United States' hospitals each year, causing up to 28,000 deaths in ICUs. The majority of patients in an ICU have a central venous catheter to ensure reliable intravenous access. However, the presence of these devices places the patients at risk for developing a CLABSI. These hospital-acquired infections are an important measure on Medicare's Hospital Compare report card portal which compares the quality of care at over 4000 Medicare-certified hospitals across the country. Hospital Compare uses the CLABSI data that the Centers for Disease Control and Prevention (CDC) collect from hospitals' ICUs via the National Healthcare Safety Network (NHSN) tool.

As CLABSI have become an important and often-used publicly reported metric, they have received much attention from quality improvement and patient safety researchers. One noteworthy study, led by Dr. Peter Pronovost and widely known as the "Keystone Project," measured the effectiveness of decreasing the rate of CLABSI by implementing various interventions across 103 ICUs. The study interventions included 5 procedures recommended by the CDC, including hand washing, using full-barrier precautions during the insertion of central venous catheters, cleaning the skin with chlorhexidine, avoiding the femoral site if possible, and removing unnecessary catheters. At the start of the study clinicians were educated about practices to control infection and harm resulting from CLABSI: a central-line cart with necessary supplies was created; a checklist was used to ensure adherence to infection-control practices; providers were stopped (in nonemergency situations) if these practices were not being followed; the removal of catheters was discussed at daily rounds; and the teams

received feedback regarding the number and rates of CLABSI. The study lasted 18 months, and demonstrated a large and sustained reduction (up to 66%) in rates of CLABSI that was maintained throughout the study period. The success of this initiative has led to the adoption of many of the best practices used in the study by ICUs across the country, particularly the use of the checklist.

Innovate and Research

When “To Err Is Human” was first released by the IOM in 1999, many of the recommendations for improving patient safety were based on anecdotal accountings of errors and expert opinion. Now, 15 years later, there is increasingly more evidence defining best practices. Critical care leaders who are committed to providing safe care for their patients should exert effort to implement these evidence-based practices. Those who want to lead in patient safety should innovate new approaches for preventing errors, and study these approaches using rigorous research methodology.

ICU-Acquired Weakness and Early Mobilization in the Intensive Care Unit

Carol Hodgson, PhD, FACP and Eddy Fan, MD, PhD

KEY POINTS

- 1 ICU-acquired weakness is common and occurs early during the ICU stay.
- 2 Bed rest is a contributing factor and may be modifiable.
- 3 Early mobilization is a promising intervention to prevent ICU-acquired weakness.
- 4 Early mobilization requires a coordinated, multidisciplinary approach.

INTRODUCTION

The decreasing mortality from critical illness over recent decades has led to an increasing number of intensive care unit (ICU) survivors.¹⁻³ As a result, there has been a shift in focus from short-term mortality to longer-term morbidities within the field of critical care. Neuromuscular complications, leading to ICU-acquired weakness (ICUAW) and impaired physical function, are common in survivors of critical illness, with a prevalence ranging from 9% to 87%.⁴ Furthermore, these complications are frequently severe and persistent, contributing to functional decline and significant decrements in health-related quality of life.⁵⁻¹¹

Reasons for muscle weakness following critical illness are multifactorial, including premorbid weakness associated with chronic diseases. Recently, there has been growing recognition that both critical illness and its associated treatments are toxic to muscles and nerves and contribute to the development of ICUAW.^{1,2} Unfortunately, there are limited interventions to prevent or treat ICUAW. There is currently evidence from observational studies and

small randomized controlled trials that establishes proof-of-principle that early mobilization (EM) may improve patient outcomes. This chapter will focus on the development, detection, and outcomes of ICUAW, with a particular emphasis on the role of EM in the critically ill. We will also discuss the barriers to EM in the ICU, the safety considerations for EM, strategies for measuring outcomes, and setting goals that include both the patient and their families.

ETIOLOGY AND PATHOPHYSIOLOGY OF WEAKNESS IN THE ICU

Bed Rest, Immobilization, and Disuse Muscle Atrophy

Prolonged bed rest and immobilization is common in many ICU patients and may contribute to the development of ICUAW.³ A meta-analysis of 39 randomized trials examining the effects of bed rest on 15 different medical conditions and procedures

demonstrated that bed rest was not beneficial, and may be associated with harm.⁴

Prolonged bed rest leads to decreased muscle protein synthesis, increased muscle catabolism, and decreased muscle mass, especially in the lower extremities.^{5,6} In healthy volunteers, muscle atrophy can begin within hours of immobility,⁷ resulting in a 4% to 5% loss of muscle strength for each week of bed rest.⁸ Immobility results in the activation of specific biochemical pathways that lead to enhanced proteolysis and decreased protein synthesis, resulting in a net loss in muscle mass, cross-sectional muscle area, and contractile strength.⁹⁻¹² Moreover, there is a general shift from slow twitch (type I) to fast twitch (type II) muscle fibers, with reduced muscle endurance due to fewer fatigue-resistant (type I) fibers.¹³⁻¹⁵ Consequently, disuse atrophy results in deleterious effects on muscle strength, with nearly 2% of quadriceps' strength lost for each day of bed rest in healthy individuals.^{16,17} In a multisite study of patients with acute respiratory distress syndrome (ARDS), the duration of bed rest during critical illness was the only risk factor consistently associated with weakness throughout the entire follow-up, with each additional day of bed rest having up to an 11% relative decrease in muscle strength at 24-months post-ARDS.¹⁸ In addition, the interaction of bed rest and critical illness appears to result in more significant muscle loss than bed rest alone.¹⁹⁻²¹ Furthermore, short-term immobility may impair microvascular function and induce insulin resistance, both of which may further potentiate injuries to muscle and nerves in the critically ill.²²

In addition to its direct effects on muscle, immobility can lead to a proinflammatory state via increased proinflammatory cytokines.^{23,24} This cytokine shift may potentiate the systemic inflammatory milieu commonly observed during critical illness leading to further muscle damage and loss.²⁵ The proinflammatory state associated with bed rest also may cause increased production of reactive oxygen species (ROS), with a concomitant decrease in antioxidative defenses.^{26,27} ROS play a role in oxidization of myofilaments, resulting in contractile dysfunction and atrophy.^{28,29} This concomitant increase in ROS and imbalance in the cytokine profile can further disrupt the balance between muscle synthesis and proteolysis, with a net loss of muscle protein and subsequent muscle weakness.

Finally, bed rest may produce indirect consequences that lead to further intolerance of physical activity. Immobility may lead to increased postural hypotension and tachycardia due to alterations in baroreceptor function.^{30,31} Furthermore, prolonged physical inactivity can result in generalized pain and changes in mood which may limit physical function.³² Even in healthy adults, the effects of prolonged immobilization and disuse atrophy alone are often persistent, and require extensive physical reconditioning to allow a return to their baseline level of functioning.^{30,31}

Critical Illness Polyneuropathy and Critical Illness Myopathy

Critical illness polyneuropathy (CIP) is a diffuse and symmetric sensorimotor axonal neuropathy that was first described in 1984.³³ Electrophysiologic changes, detected with nerve conduction studies (NCS) and electromyography (EMG), can occur within 24 hours after the onset of critical illness.³⁴ The development of primary axonal degeneration in CIP is likely multifactorial, but a number of mechanistic hypotheses have been posited.³⁵⁻³⁷ Critical illness myopathy (CIM) represents metabolic, inflammatory, and bioenergetic derangements in muscle similar to those seen in CIP.³⁸ These changes result in early and rapid skeletal muscle wasting during the first week of critical illness.³⁹ Functional inactivation of the remaining muscle may occur due to membrane inexcitability from acquired ion-channel dysfunction.⁴⁰⁻⁴² CIP and CIM share many pathologic mechanisms, often coexist, and may represent a form of neuromuscular organ dysfunction from systemic critical illness.¹ As such, similar emphasis should be placed on prevention and recovery as would be for ICU patients that develop acute kidney injury or lung injury.⁴³

Although immobilization and the effects of critical illness traditionally have been considered to predominantly affect peripheral muscles groups, recent preclinical and clinical studies have suggested diaphragmatic involvement, including reduced muscle force and increased muscle atrophy.⁴⁴⁻⁴⁶ A preliminary study in humans suggests that even short-term diaphragmatic inactivity and controlled mechanical ventilation (with effective functional denervation) can result in marked diaphragmatic

atrophy.⁴⁷ A “two-hit” combination of immobilization and the early development of subclinical CIP/CIM may contribute to the rapid development of muscle atrophy.⁴⁸

RISK FACTORS FOR ICU-ACQUIRED WEAKNESS

Although many studies have investigated risk factors for ICUAW, most have been limited by small sample size, retrospective design, and single-center experiences.⁴⁹ Furthermore, lack of comparable patient populations and standard definitions for ICUAW makes comparisons across studies difficult.^{43,49} Thus, although there are a number of commonly cited risk factors for ICUAW, many lack support from rigorous clinical investigations.⁴³

Hyperglycemia

A recent systematic review found that hyperglycemia is the most consistently identified risk factor for ICUAW.⁴⁹ Two large randomized controlled trials (RCTs) of intensive insulin therapy for tight glycemic control in the ICU,^{50,51} and associated subanalyses,^{37,52} demonstrated a substantial decrease in the incidence of ICUAW in patients randomized to intensive insulin therapy. However, the overall safety and efficacy of intensive insulin therapy and tight glycemic control in a heterogeneous population of critically ill patients remains controversial,⁵³⁻⁵⁵ and clinicians should be cautious in using the results of these secondary analysis to support the use of tight glycemic control for the prevention of ICUAW.

Sepsis and Systemic Inflammation

Given the potential mechanistic relationship between systemic inflammation (ie, the systemic inflammatory response syndrome [SIRS]), with or without concomitant infection (ie, sepsis), and the development of ICUAW, several studies have examined this issue.⁵⁶⁻⁵⁸ Two prospective studies reported a significant association of ICUAW with the presence of SIRS⁵⁷ and the duration of SIRS (odds ratio [OR] 1.05; 95% confidence interval [CI] 1.01-1.15 for each day in the first week).⁵⁶ However, another prospective study demonstrated no association between the presence of sepsis and ICUAW.⁵⁸

Corticosteroids and Neuromuscular Blocking Agents

There has been substantial controversy regarding the role of systemic corticosteroids in the development of ICUAW. A prospective study reported that exposure to corticosteroids was the single largest risk factor for the development of weakness (OR 14.9; 95% CI 3.2-69.8).⁵⁹ However, this study revealed no relationship between the dose or duration of corticosteroid therapy and the development of weakness. A number of other clinical studies, including a systematic review, have failed to demonstrate a consistent association between corticosteroids and ICUAW.^{18,37,49,56-58,60-64} Conversely, a recent study demonstrated decreased ICUAW in patients randomized to intensive insulin therapy who also received corticosteroids in the ICU (OR 0.91; 95% CI 0.86-0.97).⁵² The investigators suggested that the deleterious effects of corticosteroids on the neuromuscular system may be mediated through hyperglycemia, such that when blood glucose is strictly controlled, the anti-inflammatory effects of corticosteroids may be protective against ICUAW.

Despite early reports of persistent weakness following prolonged administration of neuromuscular blockade, 5 prospective trials,^{18,37,49,56,57} an RCT (which demonstrated a significant reduction in 28-day mortality)⁶⁵ and a systematic review⁶⁶ did not find a significant association between their use and the development of ICUAW. However, 2 other studies did find a significant association, possibly due to larger doses and longer duration of neuromuscular blockade use.^{52,61} Thus, clinicians should consider the use of corticosteroids or neuromuscular blocking agents on a case-by-case basis, weighing the potential risks and benefits based on the individual patient characteristics.⁶⁷

CLINICAL MANIFESTATION AND DIAGNOSIS OF ICU-ACQUIRED WEAKNESS

ICUAW is often difficult to diagnose in critically ill patients during the acute phase of their illness due to the frequent use of deep sedation. As a result, ICUAW is usually recognized in 2 distinct contexts: (1) prolonged or failed weaning from mechanical

ventilation, despite otherwise global improvement in other organ systems; or (2) profound bilateral weakness in an awake patient recovering from critical illness.⁶⁸ In either scenario, neuromuscular dysfunction is usually detected after the recovery of other organ systems as the patient wakes.

Typically, symmetric motor weakness is observed in all limbs, ranging from mild paresis to frank quadriplegia. In noncooperative patients, noxious stimuli may be applied to each extremity in order to grossly evaluate the strength of patient withdrawal. Since facial muscles are typically spared in patients with ICUAW, patients may have normal facial grimacing with application of noxious stimuli.

Physical Examination

The bedside physical examination of the neuromuscular system in a critically ill patient is often difficult due to deep sedation or delirium. The standard physical examination of individual muscle groups is typically done using the Medical Research Council (MRC) Manual Muscle Test scale,⁶⁹ which is dependent on patient effort and cooperation. This scale evaluates muscle strength with a score ranging from 0 (no muscle contraction) to 5 (normal strength). Physical examination of 3 muscle groups in each limb, yielding a composite MRC score, has demonstrated excellent inter-rater reliability within specific non-ICU patient populations,⁷⁰ with very good inter-rater reliability in ICU patients and survivors.⁷¹ Clinically detectable muscle weakness has been arbitrarily defined as a composite MRC score less than 80% of normal (eg, composite MRC score less than 48 out of a maximum score of 60 for 3 muscle groups in each limb).^{59,70,72} Other methods of volitional muscle testing that could be employed in these patients include handheld or handgrip dynamometry.

Similar to the motor examination, a sensory examination is often limited by sedation, altered sensorium, as well as peripheral edema. Deep tendon reflexes may be diminished or absent, but normal reflexes do not rule out ICUAW. Hyperreflexia and/or associated spasticity should suggest an alternative diagnosis (eg, central nervous system etiology), and further investigations (eg, brain and spinal cord imaging) should be obtained.

Electrophysiology and Muscle Biopsy

Given the limitations of physical examination, there has been growing interest in the use of electrodiagnostic testing (ie, motor/sensory NCS and needle EMG) for the diagnosis of ICUAW. In patients with CIP, NCS often reveal a mixed sensorimotor axonopathy manifested by a reduced amplitude of the compound muscle action potential (CMAP) and sensory nerve action potential (SNAP) with relative preservation of the nerve conduction velocity.³⁶ The electrophysiologic changes seen in CIP can be detected as early as 24 to 48 hours following the onset of critical illness, and often precede clinical findings in these patients.⁷³⁻⁷⁵ Despite their potential utility in sedated or comatose patients, there are still certain technical factors, including local edema and limb temperature, which can interfere with NCS.²

In patients with CIM, prolongation of CMAP duration on NCS can be seen and suggests the presence of a myopathic process (ie, not due to muscle denervation). On needle EMG, CIM will manifest as short-duration, low-amplitude motor unit action potentials (MUAP) with early recruitment of MUAPs on volitional contraction. Furthermore, abnormal spontaneous activity, including fibrillation potentials and positive sharp waves, may be present.⁷⁶ Therefore, diagnosis of CIM with EMG requires a cooperative patient that can perform voluntary contraction, and an experienced clinician to interpret the results.

Definitive diagnosis of an underlying myopathy requires histologic confirmation with a muscle biopsy. Histopathologic findings consistent with CIM include muscle fiber atrophy (with preferential loss of type II fibers), occasional fiber necrosis and regeneration, and selective loss of myosin filaments (pathognomonic for CIM).³⁸

Diagnostic Strategy

Despite its limitations, routine bedside physical examination should be the starting point for the identification of ICUAW. Given the relative cost, invasiveness, and need for specialist physicians and technicians, comprehensive electrophysiology studies and muscle biopsy should be reserved for weak patients with slower-than-expected improvement on serial clinical examination.⁶⁸

OUTCOMES IN PATIENTS WITH ICU-ACQUIRED WEAKNESS

Weaning From Mechanical Ventilation

Prolonged or failed weaning from mechanical ventilation is a common manifestation of ICUAW in patients recovering from critical illness. Involvement of both chest wall muscles and the diaphragm in ICUAW likely contribute to the difficulty with weaning from mechanical ventilation. In a recent systematic review, 12 of 13 studies that evaluated ICUAW and the duration of mechanical ventilation revealed that ICUAW was associated with prolonged mechanical ventilation in patients with ICUAW.⁴⁹ In one study, the presence of ICUAW was the only significant predictor of failure to wean from mechanical ventilation (OR 15.4; 95% CI 4.6-52.3).⁷⁷

Patient Outcomes After ICU Discharge

A recent systematic review was inconclusive regarding differences in patient outcomes with CIP versus CIM.⁴⁹ Existing evidence is also inconclusive regarding whether ICUAW is associated with increased hospital mortality.^{49,61,78} In survivors of critical illness, recovery from ICUAW is possible, with a majority (94%) of patients in one cohort demonstrating meaningful clinical recovery of muscle strength at 9 months.⁵⁹ However, in some patients, ICUAW may persist and result in severe and prolonged functional deficits,^{18,79-81} with concomitant decrements in health-related quality of life.^{18,82,83}

STRATEGIES FOR THE PREVENTION AND TREATMENT OF ICU-ACQUIRED WEAKNESS

There are currently few options for the prevention and/or treatment of ICUAW. During critical illness, exposure to hyperglycemia and certain medications (eg, corticosteroids and neuromuscular blocking agents) may be associated with the development of ICUAW. At present, the strongest evidence for the prevention of ICUAW is tight glycemic control with intensive insulin therapy, which may decrease neuromuscular abnormalities

in critically ill patients who are mechanically ventilated for more than or equal to 7 days. However, the potential benefits of intensive insulin therapy should be carefully weighed against the possibility of serious hypoglycemia, as demonstrated in recent clinical trials.^{55,84} Finally, despite a strong evidence base, maintenance of electrolyte homeostasis (eg, phosphate, magnesium) and adequate nutrition to ameliorate muscle catabolism may be reasonable clinical recommendations for minimizing ICUAW.⁸⁵

Beneficial Effects of Exercise in ICU

A potential therapeutic option to reduce ICUAW is avoidance of bed rest via EM in the ICU setting. EM in the ICU is a candidate intervention to improve muscle strength, physical function, and quality of survival.⁸⁶ EM is the intensification and acceleration of the usual physical therapy (PT) that is administered to critically ill patients, along with additional novel concepts that include the mobilization of patients requiring mechanical ventilation and the use of novel techniques such as cycle ergometry and electrical muscle stimulation.⁸⁶ EM is applied with the intention of maintaining or restoring musculoskeletal strength and function and thereby, potentially, improving functional, patient-centered outcomes.⁸⁷

Usual Physical Therapy in ICU

The management of critically ill patients appears to vary widely within countries and internationally.^{88,89} This is partly due to cultural differences, funding differences (eg, staffing ratios of nurses to patient), and partly due to differences in medical management as a result of local practice. To date there is no published data comparing the practice of early mobilization in ICUs internationally. However, there are 2 multicenter point prevalence studies of EM in ICU that may be informative. The first studied all patients from 38 ICUs in Australia and New Zealand at a single time on a single day in 2009 and 2010.⁸⁸ Of the 514 patients included, 45% were mechanically ventilated. Overall, mobilization activities were classified into 5 categories that were not mutually exclusive: 140 patients (28%) completed an in-bed exercise regimen, 93 (19%)

sat over the side of the bed, 182 (37%) sat out of bed, 124 (25%) stood and 89 (18%) walked. Adverse events occurred on 24 occasions (5%). Importantly, none of the mechanically ventilated patients sat out of bed or walked on the day of the study. The main barrier to mobilization was that the patient was unconscious (20%) or deeply sedated (17%).

A similar study was conducted in 116 German ICUs including 783 mechanically ventilated patients.⁸⁹ Overall, 185 patients (24%) were mobilized out of bed which was defined as sitting on the edge of the bed or a higher level of mobilization. Among patients with an endotracheal tube, tracheostomy, and noninvasive ventilation, 8%, 39%, and 53% were mobilized out of bed, respectively. This study identified cardiovascular instability (17%) and deep sedation (15%) as the main barrier to mobilization, however mobilization out of bed was not associated with a higher frequency of complications.

Safety

Clinical practice guidelines endorsed by the European Society of Intensive Care Medicine (ESICM) on the safety of EM have been published and serve as a guide to clinicians working in the ICU.⁹⁰ Active mobilization of a critically ill patient, particularly if they require mechanical ventilation, involves a complex assessment that has not been standardized and may differ between ICUs and individual patients. In part this may be due to the heterogeneity of critical illness, the changing stability of the patient and the cointerventions; however it is also affected by the individual response to EM.⁹¹

The decision to actively mobilize a patient, both in bed and out of bed, should be made by the multidisciplinary ICU team, preferably during the morning rounds. The decision should include the individual assessment of the patient's past medical history and exercise tolerance, respiratory and cardiovascular stability over the previous 24-hour period, management of lines and tubes, consideration of orthopedic and neurologic conditions, medications that may affect the patients' safety during mobilization, and the available staff and equipment to ensure patient safety. Occasionally medical staff outside the ICU may need to be consulted about the safety of mobilization, for example in a polytrauma patient with lower leg injuries, an orthopedic surgeon may need

to be contacted regarding the lower limb weight-bearing status if it is not clearly documented in the patient history.

Ideally, each ICU would formulate a protocol to guide EM, where decisions are predetermined about the safety criteria acceptable within that ICU to commence mobilization and the safety criteria to cease if the patient deteriorates during mobilization.

Cardiovascular Reserve

Cardiovascular stability is determined by assessing the heart rate and rhythm, blood pressure, requirement and dose of vasoactive or antiarrhythmic drugs, and other major cardiac conditions or support (eg, intra-aortic balloon pump, extracorporeal membrane oxygenation [ECMO]).⁹⁰ The blood pressure and heart rate should be considered stable by the medical staff, with minimal variability (< 20%) over the preceding hours and stable requirements of vasoactive drugs. If there is any doubt about cardiovascular stability, the medical team should be consulted prior to mobilization.

Respiratory Reserve

Respiratory stability is determined by the respiratory rate and pattern, the fraction of inspired oxygen and the arterial oxygen concentration measured either with blood gases or a pulse oximeter and the ventilator settings if the patient is on mechanical ventilation, including the rate, pressure, volume, and requirement for positive end-expiratory pressure (PEEP). In general, the respiratory rate and oxygen requirements should not have increased in the preceding hours prior to mobilization and the patient should have a clear airway with minimal work of breathing.⁹⁰ The oxygen saturation should be greater than 90% and the fraction of inspired oxygen 0.6 with PEEP less than 15 cm H₂O. The respiratory rate should be less than 30 breaths/min.

Prior to each episode of mobilization, an appropriate ICU staff member should check the position of the artificial airway and ensure that the artificial airway is secure (ie, an orotracheal, nasotracheal, or tracheostomy tube). Additionally, if the plan is to move away from the bed, any supplementary gas supply required by the patient during mobilization should be available and there should be adequate reserve for the expected duration of the mobility

session, and a little extra reserved for any unexpected additional requirements.

Neurologic Stability

Ideally, prior to mobilization, the patient is awake, calm, and able to follow instructions. This can be assessed with standardized tools, such as the Richmond Agitation and Sedation Scale (RASS), where a score of -1 to $+1$ is ideal. Delirium is common in the ICU and can also be assessed using the Confusion Assessment Method for the ICU (CAM-ICU). Other neurologic precautions for EM include active treatment for intracranial hypertension, craniectomy, open lumbar drains, spinal precautions, or the presence of an acute spinal injury.

Other Considerations

Medical Conditions—Patients should also be assessed with regards to oxygen carrying capacity ($Hb > 7$ g/dL and stable), white cell and platelet count, deep vein thrombosis or pulmonary embolus, body temperature, unstable fractures, skin grafting, and open surgical wounds. If there is any doubt about the safety of mobilization, the senior consultant or surgeon should be asked to make a final decision prior to commencing EM.

Staffing—There must be adequate trained staff and equipment to ensure safe mobilization of an ICU patient. In the case of a mechanically ventilated patient, one person should always be designated to ensure the security of the airway during mobilization. The patient should be assessed for strength prior to mobilizing out of bed, for example using the MRC manual muscle test, and if there is significant weakness the patient may not be strong enough to mobilize against gravity or they may require specific equipment designed to assist with EM. This may include a hoist, standing lifter or a walking frame designed to include a pole (to attach intravenous fluids), and a stand for the mechanical ventilator and oxygen tank (Figure 14–1).

Other Lines, Drains, and Attachments—Each ICU may differ in its policy regarding attachments that are safe for mobilization, or attachments that are contraindicated for mobilisation. Discussion about the safety of various patient lines and attachments must be considered on an individual basis. There is some evidence that femoral catheters,

FIGURE 14–1 A custom made walking frame on wheels, including 2 poles for intravenous fluids, a stand for the mechanical ventilator, and a frame to hold the oxygen cylinder.

including femoral catheterization for hemofiltration, should not be a contraindication to EM in the ICU.⁹² Similarly, some extracorporeal devices are considered safe for EM with adequately trained staff conducting the activities.⁹³

In a recent systematic review of physiotherapy in intensive care, 17 observational studies of EM reported outcomes regarding feasibility, safety, and physiologic effects.⁹¹ Mobilization activities were reported as both safe and feasible, with the frequency of serious adverse events reported to be less than or equal to 1%. There were occasional short-term physiologic changes associated with EM that requires careful assessment throughout the mobilization activity.

Clinical Evidence—Early mobilization in ICU is an emerging new focus of intensive critical care research, representing a potentially lower-cost, high-impact intervention. However, there are few RCTs evaluating its efficacy.

Three RCTs⁹⁴⁻⁹⁶ and a number of observational studies⁹⁷⁻¹⁰² have provided data on the safety and preliminary efficacy of the concept of mobilizing patients dependent on ventilatory support. In the first observational study, the authors described 1449 activity events in 103 patients. Overall, 53% of these events included ambulating patients that were dependent on positive pressure ventilation via an endotracheal tube or tracheostomy; there was less than 1% adverse events related to EM. This treatment was resourced from within the existing ICU staff structure, including ICU nurses, technicians, physical therapists (PTs), and respiratory therapists. In a further study, the same authors describe a before-and-after cohort study in 104 patients with respiratory failure who were transferred from another ICU to their respiratory ICU. Transfer to the study respiratory ICU with a culture of EM increased the probability of ambulation ($P < 0.0001$) during ICU stay.

Schweikert and colleagues reported findings from a prospective, outcome assessor-blinded, randomized trial of early physical therapy (PT) and occupational therapy (OT) from two centers in the USA.⁹⁵ In this study, patients who were mechanically ventilated for less than 72 hours and expected to stay ventilated in the next 24 hours were randomized either to an EM protocol which progressed from passive range of motion (PROM), active range of motion (AROM), bed mobility, sitting balance, standing, standing transfers, and gait reeducation during sedation interruption, or a control group which underwent PT and OT as prescribed by standard care. This trial demonstrated safety and feasibility for EM, as well as improved functional outcomes with early intervention.

COMMON BARRIERS TO EARLY MOBILIZATION IN THE ICU

Sedation

The aim of sedation management in ICU is to keep patients awake and comfortable where appropriate¹⁰³ and to use sedation when medically indicated in the following manner:

1. Target therapy to a desired sedation score (eg, RASS)
2. Use analgesic therapy over sedative/hypnotic therapy

3. Limit excessive doses of sedative and analgesic medications
4. Reduce the incidence of medication-induced delirium
5. Promote daily sedation interruption to facilitate early mobilization

Analgesic and sedative infusions are routinely used in the ICU in patients requiring mechanical ventilation.¹⁰⁴ Although these infusions are often required for patient comfort, to facilitate procedures and for patient-ventilator synchrony, heavy sedation ($RASS \leq -3$) is commonly used. There are some circumstances when heavy sedation is required (eg, to control raised intracranial pressure [ICP]). However, it is now understood that excessive sedation may result in delayed extubation and prolonged ICU length of stay, as well as a decrease in sleep quality, an increase in delirium, and even an increase in mortality.¹⁰⁴

Targeted sedation protocols involve the use of a validated sedation scale. Treating teams determine a required level of sedation and then titration algorithms are used to maintain the patient's level of sedation within the target range. Targeted sedation protocols have been shown to reduce time to arousal and decrease the duration of mechanical ventilation, as well as limiting exposure to benzodiazepines without an increase in self-extubation rates. A recent survey of Australian and New Zealand ICUs found that although 74% of ICUs used continuous infusions as the primary means of sedation and 70% used a sedation scale, only 48% of units had a written sedation policy.¹⁰⁴

Delirium

Assessment for delirium is recommended using either the CAM-ICU or the Intensive Care Delirium Screening Checklist (ICDSC). Delirium is known to be associated with the use of sedative medications and there is evidence that the use of a sedation protocol can decrease the number of days with delirium. The CAM-ICU tool should be used daily if the RASS score is greater than or equal to -2 . A delirious patient may be unsafe when mobilized out of bed, and particular caution is required as their behavior may be unpredictable.

Pre-ICU Level of Function

It is important to set realistic goals for mobilization based on previous levels of physical function. Communication with the family and caregivers of the patient is essential to determine premorbid level of physical function, including whether the patient could transfer from bed to chair independently prior to the critical illness. For instance, it is essential to determine if the patient previously walked independently or with a gait aid, whether they could walk outside, on uneven surfaces, to the mailbox, around the shops, or further? Patients who were unable to walk independently or transfer independently prior to ICU admission will require increased supervision and increased staff numbers when attempting mobilization. This reduces the risk of injury to both patients and staff.

MEASURING EARLY MOBILIZATION IN ICU

Mobility milestones are the most commonly reported outcome measure in ICU research projects of early mobilization.¹⁰⁵ Several studies have reported mobility milestones, such as sitting, standing, or walking, as an important indication of patient physical function in ICU.^{97,99,101} They have not reported the level of assistance required to achieve the mobility milestone and they have not reported the same milestones. A recent systematic review described measures of physical function used in studies investigating EM in the ICU.¹⁰⁵ The ability to perform activities of mobility, or mobility milestones, was the most common end point reported in these studies. However, between these studies there was no consensus on the functional activities that should be included in measures of mobility in the ICU, or reports of the feasibility or inter-rater reliability of such measures.¹⁰⁵

ICU Mobility Scale

The IMS is an 11-point ICU mobility scale (Table 14-1).¹⁰⁶ The IMS was based on functional patient activities that can reasonably be achieved across the spectrum of recovery while in the ICU. Moreover the reliability assessment was conducted at 2 large ICUs with a varied clinical case mix, including surgical, medical, and trauma patients, and included nurses and junior and senior PTs.

Despite the busy ICU environment, the IMS was administered with ease. The inter-rater agreement in the scale was excellent between PTs and good between nursing staff and PTs. This simple scale of mobility milestones will not replace other tests of physical function, but may assist as a daily record of mobility for both clinical and research purposes in order to allow greater standardization and comparability across time and between ICUs.

Other measures of mobilization have been developed for specific patient groups. For example, the Surgical Intensive Care Unit Optimal Mobility Score (SOMS) consists of a simple numeric scale that describes patients' mobilization capacity in a surgical ICU. A SOMS of 0 indicates that no mobilization should be considered. This score was assigned to patients who were either moribund or had an unstable head or spinal cord injury; those in whom any change in position led to profound respiratory or hemodynamic changes; and those with elevated ICPs (> 20 cm H₂O). A SOMS of 1 was used to describe patients receiving PROM exercises while in bed, and SOMS 2 was given to patients who were able to sit up in bed greater than 45° or in a chair. A SOMS 3 described patients who were able to stand with or without assistance, and a SOMS of 4 was assigned to patients able to ambulate. The SOMS demonstrated that in surgical critically ill patients presenting without preexisting impairment of functional mobility, it is a reliable and valid tool to predict mortality and ICU and hospital length of stay.¹⁰⁷

Protocols

Several types of protocols have been suggested to allow mobilization in the ICU to occur as early as possible.^{99,107} All protocols include a stepwise prescription of mobilization activity based on the physical capacity of the patient (Figure 14-2). Protocols such as these have been safely and effectively introduced into clinical practice. Further to this, a protocol that considers both the cognitive and the physical capacity of the patient has been implemented in one center in the United States, and resulted in patients walking at least 3 days sooner, an adverse event occurrence of less than 1% and an increase in mobility of up to 2-fold.¹⁰⁸ In another US center, an increase in routine mobilization occurred.⁹⁵

TABLE 14–1 ICU mobility scale.²⁷

	Classification	Definition
0	Nothing (lying in bed)	Passively rolled or passively exercised by staff, but not actively moving.
1	Sitting in bed, exercises in bed	Any activity in bed, including rolling, bridging, active exercises, cycle ergometry, and active assisted exercises; not moving out of bed or over the edge of the bed.
2	Passively moved to chair (no standing)	Hoist, passive lift or slide transfer to the chair, with no standing or sitting on the edge of the bed.
3	Sitting over edge of bed	May be assisted by staff, but involves actively sitting over the side of the bed with some trunk control.
4	Standing	Weight bearing through the feet in the standing position, with or without assistance. This may include use of a standing lifter device or tilt table.
5	Transferring bed to chair	Able to step or shuffle through standing to the chair. This involves actively transferring weight from one leg to another to move to the chair. If the patient has been stood with the assistance of a medical device, they must step to the chair (not included if the patient is wheeled in a standing lifter device).
6	Marching on spot (at bedside)	Able to walk on the spot by lifting alternate feet (must be able to step at least 4 times, twice on each foot), with or without assistance.
7	Walking with assistance of 2 or more people	Walking away from the bed/chair by at least 5 m (5 yd) assisted by 2 or more people.
8	Walking with assistance of 1 person	Walking away from the bed/chair by at least 5 m (5 yd) assisted by 1 person.
9	Walking independently with a gait aid	Walking away from the bed/chair by at least 5 m (5 yd) with a gait aid, but no assistance from another person. In a wheelchair-bound person, this activity level includes wheeling the chair independently 5 m (5 yd) away from the bed/chair.
10	Walking independently without a gait aid	Walking away from the bed/chair by at least 5 m (5 y) without a gait aid or assistance from another person.

Goal Setting

Setting goals for rehabilitation, particularly EM, is important to patients, family, and the staff in ICU. Functional rehabilitation can be progressed based on the clinical assessment discussed previously in this chapter and may be an important motivation for critically ill patients to recover. Family and friends often express delight at finding the patient out of bed, standing, or walking, even while attached to mechanical ventilation. Concerns about safety of early mobilization may arise from visitors to the ICU and it is important for clinicians prescribing and delivering exercise to explain the physiologic response expected in these circumstances and the safety precautions utilized by ICU staff.

Goals of EM should be clearly documented and progress reported. This is required both for hospital records and for patients and their families to celebrate progress. Diaries, journals, photographs, and documentation of progress made available to the patients and their families may be beneficial for physical and psychological recovery.^{106,109,110}

PRACTICAL TIPS FOR STAFF PERFORMING EM

The S.T.A.N.D. Principle

Safety and stability: Assess the respiratory, hemodynamic and neurologic stability, muscle strength, and cooperation of the patient. Most

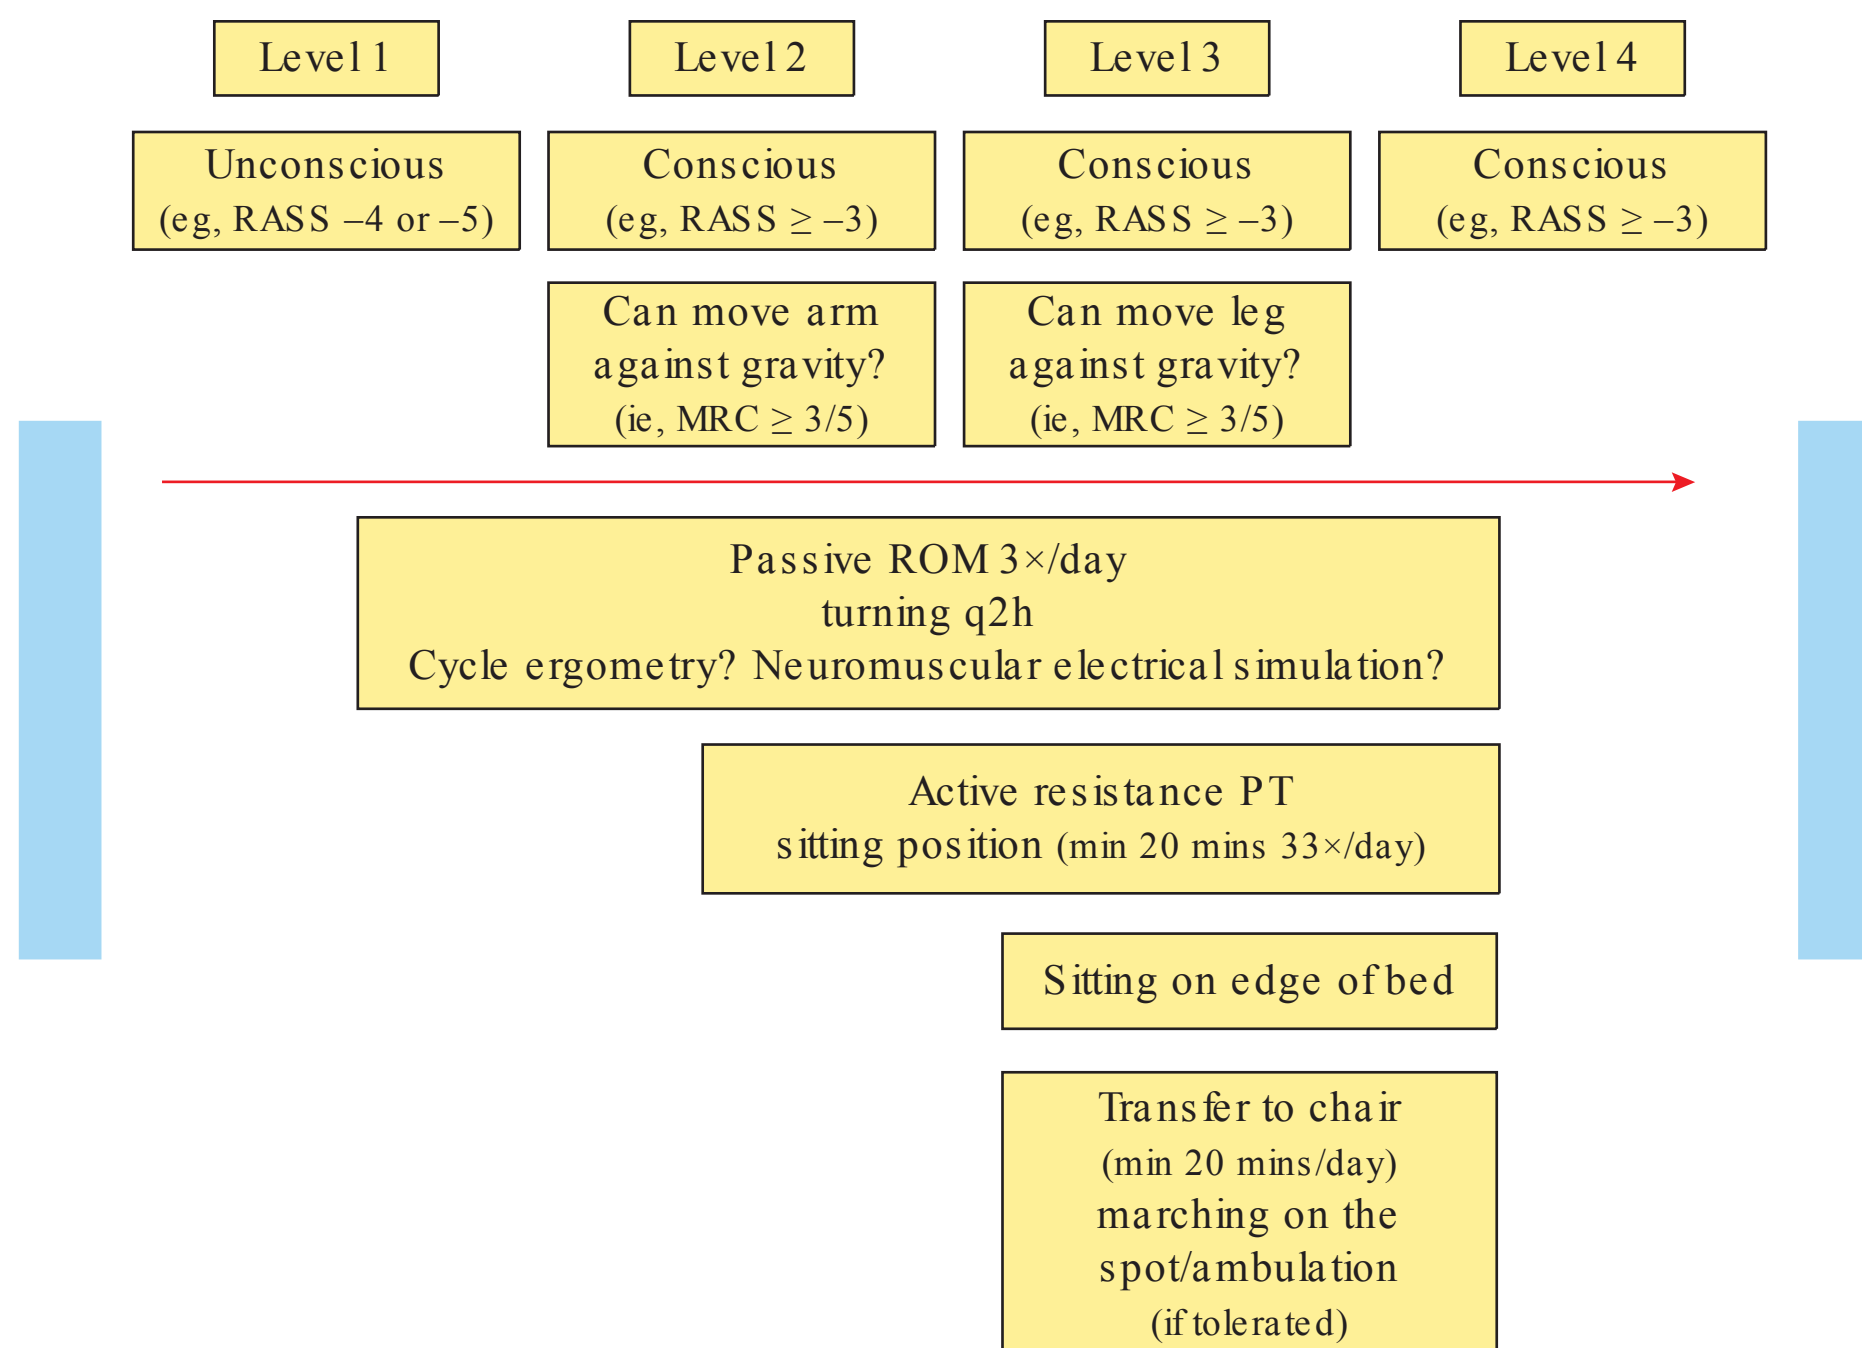

FIGURE 14–2 An example of a graded early mobilization protocol for ICU patients. Patients are initially assessed for their level of consciousness and motor strength to determine the highest level of activity they can start at. It is important to note that patients can skip directly to any level, as long as it is safe and feasible to do so, and they do not need to progress through the levels sequentially if they are capable of a higher level of activity. ICU, intensive care unit; MRC, Medical Research Council; PT, physical therapy; RASS, Richmond Agitation-Sedation Scale; ROM, range of motion.

importantly, discuss this with the ICU team if any concerns are raised prior to mobilization.

Teamwork: Early mobilization requires a team of people to work together with clear communication and an understanding of the safety requirements of the ICU. One person should be appointed as the leader of the team to direct the mobilization activity. The leader ensures that everyone in the team knows their role, including one person to be dedicated to protecting the airway.

Airway management: Airway management is the main priority during mobilization. One person is dedicated to maintaining the airway. Emergency equipment and portable oxygen supplies are checked and should remain easily accessible at all times. The patient should be suctioned prior to mobilizing and suction equipment should be available during EM.

Number of lines/tubes/attachments and equipment: Prepare the environment by

double checking that all lines and tubes are secure, the area is clear of hazards, and the equipment required for mobilization is prepared.

Determine an alternate plan: If the patient does not tolerate the mobilization activity, have an alternative plan for repositioning the patient into sitting or supine. Be prepared for bowel movements and ensure there is adequate staff around to assist if the patient becomes unstable.

FUTURE DIRECTIONS

ICU survivors recovering from a prolonged critical illness often have severe muscle weakness and functional impairment. Future studies are needed

to further elucidate the various mechanisms that lead to ICUAW, and to find and develop therapeutic targets for this morbid ICU complication. Early mobilization is a promising intervention to prevent or attenuate ICUAW and requires a coordinated, interprofessional team approach to assess readiness to mobilize and to optimize the progression of patient activity. Observational studies and small randomized trials evaluating EM suggest safety and feasibility, but are mostly single center in design with limited external validity. These studies also suggest that EM has the potential to improve functional outcomes in these survivors, reduce readmissions, and reduce health care costs. Further research is warranted to define baseline standard practice, identify risk factors that predict patients at risk of weakness, and define an intervention and intervention dose for EM.

TAKE HOME POINTS

- ICUAW is common, occurs early in critical illness, and is associated with significant long-term morbidity, and potentially mortality.
- Despite its limitations, routine bedside physical examination should be the starting point for the identification of ICUAW. Given the relative cost, invasiveness, and need for specialist physicians and technicians, comprehensive electrophysiology studies and muscle biopsy should be reserved for weak patients with slower-than-expected improvement on serial clinical examination.
- Early mobilization is a promising intervention to prevent or attenuate ICUAW.
- Early mobilization requires a coordinated, interprofessional team approach to assess readiness to mobilize and to optimize the progression of patient activity.

Pharmacology in Critical Illness

Julie Chen, PharmD, BCPS and Adam Keene, MD

KEY POINTS

- 1 Complex pharmacokinetic and pharmacodynamic variations occur in critically ill patients secondary to underlying illness and acute organ failures as well as the multiple supportive modalities employed.
- 2 Failure to appreciate variabilities in pharmacokinetic and pharmacodynamic characteristics may contribute to suboptimal dosing, adverse outcome, increased risk of medication errors and adverse drug reactions.
- 3 Altered drug absorption, plasma protein binding, volume of distribution, renal and hepatic clearance, and affinity of binding to target receptors in critically-ill patients can all affect the therapeutic response and clinical outcome.
- 4 For medications with monitoring parameters available and a fairly rapid onset of action, careful dose titration based on clinical observation is appropriate; many of the cardiovascular active agents fall into this category.
- 5 For medications with slower onset of action and dose-dependent pharmacology, proper loading and maintenance doses should be determined; changes in drug volume of distribution and clearance observed or measured in individual patients should be taken into consideration.
- 6 Therapeutic drug monitoring (TDM) is recommended for certain medications, including some antimicrobials, antiepileptics and cardiovascular agents. These tests are widely available with quick turnaround time for the results to assist in dose adjustment.
- 7 Different renal replacement regimens may have different impacts on the volume of distribution and clearance of each medication. Dosing need to be tailored to the dialysis modality utilized and delivered. In general, higher doses and more frequent dosing are necessary with continuous renal replacement therapy as compared to intermittent HD.
- 8 Other supportive modalities, such as ECMO and plasmaphoresis, can also affect the pharmacology of some medications.
- 9 Polypharmacy is inevitable in critically ill and may contribute to adverse outcome secondary to drug interactions or toxicity; careful monitoring and patient assessment remains the key for optimal therapeutic outcome.

INTRODUCTION

Medication errors and adverse drug reactions (ADRs) occur more frequently in critically ill patients due to complex polypharmacy, frequent off-label drug use and multiorgan dysfunction. Requests to provide “STAT” doses during emergent situations further complicate this issue. Clinicians require an adequate knowledge of drug pharmacokinetics (PK) and pharmacodynamics (PD) to ensure safe and effective drug use in intensive care units (ICUs).

PK describes the movement of a drug through the body including the processes of absorption, distribution, metabolism, and elimination. PD describes the physiologic effects once the drug reaches the site of action. Most PK data are derived from healthy volunteers or from stable patients with specific disease states and may not be applicable to critically ill patients. Failure to anticipate significant changes in PK and PD in critical illness may contribute to suboptimal patient management.

PHARMACOKINETIC CONSIDERATIONS

Volume of distribution (Vd) and clearance (CL) are the 2 most important PK parameters for appropriate drug dosing. Initial loading dose (LD) is determined by Vd whereas maintenance dosing (MD) is determined by CL. Alterations of Vd and CL can occur during critical illness. These changes may result in an increased pharmacologic effect and/or undesired toxicity. The following provides a brief review focusing on general principles related to drug PK and changes that can occur during critical illness. All discussion is based on a one-compartment model using first-order PK principles.¹⁻⁶

Absorption of medications from the gastrointestinal (GI) tract during critical illness is frequently low due to shunting of blood flow to support vital organs. Poor peripheral perfusion also impairs systemic absorption from muscles and subcutaneous tissues. Thus, intravenous (IV) administration is usually preferred for patients in shock. However, oral administration may be considered once patient is hemodynamically stable and enteral feeding is tolerated. Medications such as antihypertensive agents can be titrated to the

effect and provide smooth blood pressure coverage when given orally as compared to the intravenous alternatives. Some antimicrobial agents, such as cotrimoxazole, quinolones, linezolid, fluconazole, and voriconazole, have excellent oral bioavailability and can safely be given enterally once the infection is under control.

Vd is calculated by dividing the amount of drug in the body by the plasma concentration. Drug distribution in the body depends on blood flow, body composition, and plasma protein binding (PPB). In general, drugs that have high PPB stay mainly in the intravascular space and have a small Vd (Table 15–1). Lipophilic drugs have a large Vd because they tend to diffuse into the tissue and have a low plasma concentration. Vd can be used to determine the LD required to achieve a desired serum drug concentration ($C_{p_desired}$) by using the following equation (Equation 15–1):

$$LD (mg) = C_{p_desired} (mg/L) \times Vd (L/kg) \times weight (kg) \quad (15-1)$$

After appropriate fluid resuscitation, patients in septic shock and other forms of multiorgan dysfunction tend to have both greatly increased intra- and extravascular fluid volume. This can increase the Vd for hydrophilic medications significantly. Thus, much higher initial dose (LD) is required to achieve a desired therapeutic effect for a hydrophilic drug such as vancomycin and aminoglycosides. Lipophilic drugs have larger Vd and their Vd is usually not affected by the fluid shift.

PPB may affect the Vd and the therapeutic effect of a drug. Only free or unbound drugs can be readily distributed into tissues and thus have pharmacologic effect. Albumin and alpha 1-acid glycoprotein (AAG) are 2 primary proteins. Acidic drugs, such as phenytoin, bind to albumin whereas basic drugs, such as lidocaine, bind to AAG. The increased vascular permeability and protein catabolism seen in critically ill patients can result in decreased albumin concentrations. Thus, increased free plasma concentration for acidic drugs. AAG, an acute phase reactant, is increased in critically ill patients, thus, decreasing the free plasma concentration of basic drugs. Metabolic abnormalities, uremia, and drug interactions may further displace a drug from PPB. Warfarin, a drug frequently avoided in ICU patients, is 99% PPB with only 1% free drug responsible for its

TABLE 15–1 Medications with high plasma protein binding.

Drug	PPB (%)
Antiepileptics	
Phenytoin	88-93

Hydralazine	88-90

therapeutic effect. A displace of 1% PPB can double its free drug in the plasma and cause excessive anti-coagulation. Meanwhile, phenytoin is approximately 90% bound to albumin and can be displaced in uremia. It is important to recognize that these patients frequently have a low measured total phenytoin level with adequate free phenytoin level (1-2 µg/mL) for therapeutic effect. Equations have been proposed to account for increased free plasma phenytoin in patients with hypoalbuminemia (Equation 15–2) and uremia (Equation 15–3).

$$C_{\text{adjusted}} = \frac{C_{\text{measured}}}{0.2 \times \text{Alb} + 0.1} \quad (15-2)$$

$$C_{\text{adjusted}} = \frac{C_{\text{measured}}}{0.1 \times \text{Alb} + 0.1} \quad (15-3)$$

C_{measured} and C_{adjusted} : measured and adjusted phenytoin concentrations.

Alb: patient's albumin levels in g/dL.

As explained above, a patient with a serum albumin of 2 g/dL will only need a measured phenytoin level between 5 and 10 µg/mL to maintain a therapeutic effect. In the presence of uremia, a measured level between 3 and 6 µg/mL may be adequate. Although only supported by limited data, these equations are useful in ICU setting to guide dosage adjustment. Monitoring free phenytoin concentration may be impractical due to rapid changes in serum albumin levels and slow laboratory turnaround times.

CL measures drug removal from the body by all elimination pathways, including metabolism and excretion. To maintain therapeutic effect, the amount of drug removed during the dosing interval should be replaced as maintenance dose. In critically ill patients, both hepatic and renal CL is usually reduced. However, in early stage of septic shock, a compensatory hyperdynamic phase accompanied by an increase in cardiac output and organ perfusion may result in increased drug clearance. Appropriate dosage adjustment is critical to provide the desired effect while minimizing toxicity. Serum creatinine (SCr) and urine output are frequently monitored to estimate the extent of renal dysfunction. However, changes in SCr lag behind changes in actual renal

function during acute kidney injury and recovery. Also, extensive muscle injury or drug interactions (ie, concurrent trimethoprim) may cause elevated SCr unrelated to renal dysfunction. Monitoring the trend of organ dysfunction for proactive dosing adjustments is recommended. Maintenance dose for medications mainly cleared renally should be reduced in patients with oliguria or anuria, while prompt dosing increase is imperative with renal recovery. Various dosing guidelines are available based on the estimated creatinine clearance (CrCl) using Cockcroft-Gault equation (Equation 15–4):

Estimated CrCl (mL/min) for males =

$$\frac{(140 - \text{age}) \times \text{weight} * (\text{kg})}{72 \times \text{SCr}} \quad (15-4)$$

($\times 0.85$ for females—adjust for smaller muscle mass)

*Ideal body weight (IBW) should be used for obese patients:

$$\text{IBW (kg) for females} = 45 + 2.3 \times (\text{height in inches} - 60)$$

$$\text{IBW (kg) for males} = 50 + 2.3 \times (\text{height in inches} - 60)$$

It is important to know that this estimate is not reliable in patients with acute changes in SCr or very low SCr. In addition to estimated CrCl, extent of dose reduction should be based on the trend in renal function, and the indication for therapy. T is is especially important to avoid inadequate dosing of antibiotic therapy. MD adjustment can be done by either dose reduction or interval extension. Dosing for many cardiovascular drugs (ie, antihypertensive and inotropic agents), analgesics and central nervous system (CNS) depressants can be initiated conservatively and titrated to desired effect based on clinical assessment. It is also important to remember that toxic or active metabolites (ie, of opiates and benzodiazepines) may also accumulate in patients with renal dysfunction; close monitoring is required when an extended duration of therapy is indicated. Goal-directed sedation and sedation vacations are probably the most useful approaches to avoid excessive sedation in ICU patients with multiorgan failure.

Metabolism may be affected by decreased hepatic blood flow, altered PPB, decreased hepatic enzyme activity, and other metabolic abnormalities

seen in critically ill patients. Concurrent renal and cardiac dysfunction further complicates this issue. Acute hepatic dysfunction usually does not affect drug metabolism significantly. Extent of hepatic dysfunction cannot be quantified for dosage adjustment in acute or chronic liver failure. Dosing for medications that require hepatic metabolism should be initiated conservatively and titrated to the effect based on risk and benefit assessment. Concurrent or excessive use of hepatotoxic agents such as acetaminophen should be avoided whenever possible.

Half-life ($T_{1/2}$), the time required for plasma drug concentration (C_p) to reduce by 50%, is determined by Vd and CL as shown in Equation 15–5:

$$T_{1/2} = 0.693 \times \frac{V_d}{CL} \quad (15-5)$$

$T_{1/2}$ is increased with a decrease in CL, or an increase in Vd. Under normal circumstance, 4 to 5 half-lives are required for serum drug concentrations to reach steady state after a therapy is started. It may take much longer for an ICU patient to reach steady state due to rapid changes in CL and Vd. When a drug regimen is discontinued, it also takes 4 to 5 half-lives for a drug to be cleared from the plasma compartment. Dosing strategy is frequently determined by the $T_{1/2}$. For drugs with long $T_{1/2}$ (such as amiodarone with a $T_{1/2}$ of 1 month or longer with chronic use) initial LDs are required to achieve a more rapid therapeutic response. On the other hand, aminoglycosides (AGs) have a short $T_{1/2}$ of 1 to 2 hours in patients with normal renal function. Serum concentration would approach 0 before the next dose for once-a-day AG regimen. T is dosing approach utilizes the concentration-dependent killing effect of AG to enhance bactericidal action while lowering the risk of nephrotoxicity. T e post-antibiotic effect of AGs allows for continued bacterial killing even when trough concentrations of 0 are reached.

Specific PD considerations Medications with long $T_{1/2}$ do not always have a long duration of action. T is is especially true for CNS depressants including opioids, benzodiazepines, and barbiturates. T ese agents are highly lipid soluble and have a rapid onset of action after an IV dose. However, disproportion to the relatively long $T_{1/2}$, the duration of action is frequently short lived secondary to

a rapid decline of CNS concentration after a rapid redistributed into peripheral “lipid-rich” tissues. Clinical experience has shown that the effect and duration of these medications also depends heavily on the past exposure history of the patient. Patients with chronic use of alcohol, opioids, and benzodiazepines tend to develop tolerance to these agents and require much higher doses and more frequent dosing for the required sedative or analgesic effect. Receptor desensitization and/or downregulation may be responsible for this observation. In these patients, medications with long $T_{1/2}$, such as diazepam and chlordiazepoxide may still accumulate after repeated doses. The rationale of repeating the doses of benzodiazepines until the patient is calm in the acute management of alcohol withdrawal. At this stage, enough benzodiazepine accumulates in the tissue (adipose) to sustain adequate concentration in the CNS. Further doses may be used less frequently and as needed for recurrent symptoms of delirium tremens (DT). The amount accumulated in the tissue will serve as a drug depot to support a slow benzodiazepine taper and complete DT management. It is also important to recognize that all benzodiazepines will have longer duration of action and longer half-lives once the agent is accumulated in the tissue. Thus, a short-acting agent, such as midazolam, may have a long-lasting sedative effect with prolonged use.

Because of increased multiple-drug resistance infections, some specific PD-based antibiotic dosing approaches have been advocated. Aminoglycoside antibiotics have concentration-dependent killing and a pronounced postantibiotic effect. Once-daily AG regimens (gentamicin and tobramycin: up to 7 mg/kg; amikacin: up to 20 mg/kg) can achieve high peak serum concentrations with better bactericidal effect than the same dose divided into multiple doses per day. Beta-lactam antibiotics, such as piperacillin/tazobactam, have time-dependent killing. Maintaining serum beta-lactam concentrations above the minimum inhibitory concentration (MIC) during the dosing interval can achieve better antibacterial activity. When piperacillin/tazobactam is administered as an extended infusion over 4 hours, compared to a 30-minute bolus infusion, serum concentration can be maintained above the MIC for a greater proportion of time during the dosing interval.

EXTRACORPOREAL DRUG CLEARANCE

Renal Replacement Therapy

In addition to intermittent hemodialysis (IHD), continuous renal replacement therapy (CRRT),⁷⁻⁹ especially continuous venovenous hemofiltration (CVVH) and continuous venovenous hemodiafiltration (CVVHDF), is often provided to ICU patients with acute and chronic kidney injury. Removal of solutes and fluid from blood through semipermeable membranes occurs by means of either diffusion and/or convection during RRT. While IHD utilizes diffusion for clearance, CVVH utilizes convection and CVVHDF utilizes a combination of both. Small molecules (MW < 1000 Da) are removed effectively by IHD with conventional hemofilters (small pores). Modern high-flux membranes (large pores) utilized in CRRT are permeable to large molecules (30,000-50,000 Da) and therefore, most drug molecules. The characteristics of high-flux hemofilters and the continuous, prolonged nature of CRRT result in efficient solute removal and enhanced drug clearance. In general, the relative extent of drug removal in CRRT is CVVHDF greater than CVVH greater than IHD. However, the extent of CRRT clearance still depends on specific physiochemical properties of the drug and how CRRT is prescribed and delivered. Compared to IHD or patients with renal failure, drugs that are normally cleared by the kidney may require a much higher dose during CRRT. Drugs with a high V_d (> 1 L/kg), high PPB (> 80%), and predominant nonrenal clearance may need no dose adjustment due to poor CRRT removal.

Only unbound and water-soluble drug molecules are removed effectively during CRRT. It is evident that an increase in unbound fraction secondary to changes in systemic pH, plasma protein concentrations, organ function, and drug interactions can contribute to increased CRRT elimination. Another potential mechanism for solute removal during CRRT is “adsorption.” The clinical significance of drug adsorption to the dialysis circuitry and membrane is unclear. Many published data are available to guide proper drug dosing in CRRT. However, these dosing recommendations have been derived from diverse patient populations in which different

modes of CRRT were prescribed. Other clinical and patient variables, such as interruptions or inconsistency of CRRT delivery, fluid overload, and residual renal function, may also affect drug clearance. Thus, dosing in patients requiring CRRT needs to be individualized. Drugs such as analgesics, sedatives, and cardiovascular agents can be dosed based on clinical response. Therapeutic drug monitoring (TDM) is available for some antiepileptics, antimicrobials, and cardiovascular agents. The turnaround time for TDM should be short enough for the monitoring to be clinically relevant.

As a general rule, a proper LD is usually required for an agent with a long $T_{1/2}$ to achieve therapeutic plasma levels rapidly. This initial dose is determined largely by the Vd of the drug and need not be adjusted in CRRT. However, Vd might be increased significantly in ICU patients as described in the PK section. Using vancomycin as an example, a regular or even higher LD (25 mg/kg or more) should be administered initially. Subsequent MDs require modification based on the PK and PD characteristics, and CRRT clearance. For medications such as most beta-lactam antibiotics that are renally cleared, 50% to 100% of the regular MD has been recommended for patients undergoing CRRT. It is important to recognize that aggressive antibiotic dosing during CRRT along with proper monitoring is always preferred to underdosing in patients with septic shock, especially within the first few days of therapy. The nurse in charge of the CRRT delivery should also document the actual delivery of CRRT and must inform the physicians and pharmacists if any significant interruptions of CRRT occur. This information should be communicated every 6 to 8 hours, if not more often, to ensure timely dosing adjustment. This rule should also be followed when CRRT is discontinued or a different CRRT mode is prescribed.

Plasmapheresis and Therapeutic Plasma Exchange

These are automated extracorporeal apheresis techniques designed to remove or reduce the concentration of large-molecular-weight substances such as immunoglobulins and autoantibodies from the plasma. This treatment may increase drug CL.

During the process, plasma proteins are removed. Drugs with a small Vd and/or high PPB, such as basiliximab, ceftriaxone, and propranolol, may be removed significantly and supplemental doses may be required at the completion of plasmapheresis. Another approach to retain drug efficacy is to schedule the plasmapheresis toward the end of the dosing interval, allowing the regular dose to be administered at the completion of the session.¹⁰

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO)^{11,12} is an advanced life support system to provide support for patients with respiratory and/or cardiac failure who have failed conventional management. ECMO may influence PK through hemodilution (increased Vd) as well as by binding or sequestration of drugs in the ECMO circuit. Significant sequestration of opioids (fentanyl, morphine), benzodiazepines (diazepam, lorazepam, midazolam), nitroglycerin, propofol, and antimicrobials (ampicillin, cefazolin, voriconazole) has been reported. This sequestration can lower serum drug concentrations and potentially reduced the therapeutic effect. There is limited data available to guide dosing adjustment in adult patients. Most of the data have been derived from pediatric populations. Decreased serum levels of gentamicin, heparin, phenobarbital, phenytoin, and vancomycin have been reported in neonates maintained on ECMO. It is important to note that children supported by ECMO require a relative larger volume (compared to their body size) to prime the circuit and blood transfusion is frequently utilized to maintain acceptable hemoglobin levels. Although pediatric data may not be applicable to adults, higher LD and MD may be needed to maintain therapeutic levels in adult ICU patients requiring ECMO support. Proper monitoring to guide dose adjustment is essential. Serum drug monitoring is not possible for many drugs used in ICU. Tailoring therapy to the individual clinical response is often a more practical approach.

Dosing Adjustment in Obese Patients

Most recent reports indicate that 12% to 37% of ICU patients are obese. Obesity presents unique

challenge because only limited PK data are available to guide dosing. Many drug investigations either exclude or do not include enough obese patients for data extrapolation. In general, both V_d and CL of drugs are altered by obesity. Lipophilic medications are distributed to adipose tissue and a larger dose is required to achieve therapeutic serum or tissue levels. Loading doses of lipophilic agents, such as phenytoin, should be based on the actual body weight followed with MD adjusted based on serum concentrations. Also, higher doses of sedatives and opioids (most are lipophilic) are usually required initially for the desired sedative or analgesic effect. However, obese patients are also at increased risk for drug accumulation after prolonged infusion or frequent dosing. Thus, proper dose titration to goal or patient response is essential. More hydrophilic medications with smaller V_d and limited distribution to adipose tissue may be dosed based on adjusted weight as per Equation 15–6.¹³

$$\text{Adjusted body weight} = \text{ideal body weight} + 40\%(\text{actual body weight} - \text{ideal body weight}^*) \quad (15-6)$$

*See Equation 15–4 for ideal body weight.

Since most antimicrobial agents are hydrophilic, adequate blood concentrations may be achieved at the usual recommended doses. However, more aggressive antibiotic dosing approaches may be indicated based on the severity of the infection and the safety profile of the agent chosen. Again, with limited data to support dosing, seeking assistance from an experienced clinical pharmacist is recommended. Close monitoring for drug efficacy and toxicity is essential in the management of obese ICU patients.

Therapeutic Drug Monitoring

Serum drug concentrations of some medications may need to be monitored to ensure therapeutic effect without excessive toxicity (Table 15–2). Timing of a blood sample in relation to previous dose influences the interpretation of a drug concentration measurement. As a general rule, TDM should be done when steady state has been reached (after 4–5 half-lives). Check a peak level “immediately” after a LD is rarely justified. To confirm if a LD is adequate

TABLE 15–2 Therapeutic ranges for drugs commonly used in ICU.

Drugs	Therapeutic Range ^a
Amikacin	Peak: depends on dosing strategy and severity/site of infection Trough < 5 µg/mL
Carbamazepine	4–12 µg/mL
Gentamicin	Peak: depends on dosing strategy and severity/site of infection Trough < 2 µg/mL
Digoxin	0.5–1.2 µg/L
Phenobarbital	15–40 µg/mL
Phenytoin	Total: 10–20 µg/mL Free ^b : 1–2 µg/mL
Theophylline (in COPD)	5–10 µg/mL
Tobramycin	Peak: depends on dosing strategy and severity/site of infection Trough < 2 µg/mL
Valproic acid	50–140 µg/mL
Vancomycin	15–20 µg/mL (10–15 is acceptable for less severe infections)

^aTrough level is preferred unless otherwise specified.

^bAlthough free phenytoin levels are occasionally indicated or recommended, they are not practical in critically ill patients secondary to slow test turnaround times and rapid changes in serum albumin (see text for details).

or further LD is needed, the level should be checked after the completion of the distribution phase. Most drugs, such as vancomycin and aminoglycosides, have a distribution phase of 30 to 60 minutes after IV administration. Digoxin is an exception to this rule. The distribution phase of digoxin is prolonged and a level (if indicated) should be drawn at least 4 to 6 hours after an IV dose or 6 to 8 hours after an oral dose. Otherwise, the measured serum digoxin level will be falsely high and misleading. Although a peak level may be required for some medications (ie, AGs), most drug levels should be checked as steady-state troughs just before the next dose is due. These trough levels represent the lowest level in the blood which can be used to guide dose adjustment based on clinical assessment. If trough monitoring is not feasible, another approach is sampling

blood for drug levels consistently during a dosing interval after the completion of distribution phase. T is means drawing a level at the same time of the day when such monitoring is indicated. T e trend of serum drug concentration changes can then be used to guide MD adjustment. After a target level is achieved, drug levels only need to be rechecked as clinically indicated such as in patients with acute changes in organ function, suspected toxicity, or clinical failure. Also, it is important to allow at least 2 to 4 hours to elapse after any form of renal replacement therapy before sampling blood if a drug level is indicated. T is is to allow redistribution of the drug from other tissues into the intravascular space. Otherwise, a falsely low level may lead to unnecessary dosing increase. T e extent of this rebound of serum concentration after dialysis is more significant for a drug with a larger Vd and/or after prolonged therapy secondary to increased tissue drug accumulation.

Adverse Drug Events

Adverse drug events (ADEs)¹⁴⁻¹⁷ are defined as harm or injury caused by the use of a drug. T ese events can occur at any stage in treatment. Approximately 25% of ADEs are either unpredictable or caused by an allergic reaction. T e rest ADRS (> 70%) are dose related or predictable based on pharmacologic characteristics. Critically ill patients are at high risk for ADEs because of their organ dysfunctions as well as the complexity of the medications they are prescribed. Acute renal failure in ICU patients has been linked to increased morbidity/mortality, length of stay, and cost. Up to 20% of all cases of renal failure in ICUs may be associated with drug toxicity. T e benefit of using any nephrotoxic agent (Table 15–3) in ICU patients needs to be weighed against the risk. Patients should be monitored carefully and evidence-based preventive measures should be provided whenever possible. Efforts should also be directed to minimize the exposure to other potential causes of renal injury. Adequate hydration with isotonic fluid and maintenance of renal perfusion are crucial for reducing renal toxicity associated with many agents including acyclovir, amphotericin B, radiocontrasts, and sulfonamides. Aggressive diuretic therapy should be used with caution when a patient is maintained on a therapy with known nephrotoxicity. If drug-induced renal failure is suspected,

TABLE 15–3 Medications frequently associated with nephrotoxicity in ICUs (not all inclusive).

Angiotensin-converting enzyme inhibitors/angiotensin receptor antagonists Captopril Lisinopril Losartan, etc
Antimicrobials Aminoglycosides—amikacin, gentamicin, tobramycin, etc Amphotericin B—including all lipid complex formulations Antivirals—acyclovir, foscarnet, cidofovir, pentamidine Beta-lactams—penicillins and cephalosporins may cause interstitial nephritis in rare cases Sulfonamides—sulfadiazine, sulfamethoxazole, etc
Calcineurin inhibitors Cyclosporine Tacrolimus
Diuretics—secondary to intravascular volume depletion Bumetanide Furosemide Torsemide
Nonsteroidal anti-inflammatory agents (include cyclooxygenase-2 inhibitors) Ketorolac Ibuprofen Naprosyn, etc
Miscellaneous Allopurinol Immunoglobulins Mannitol Radiocontrasts Starches—hetastarch, etc

the therapy should be discontinued whenever possible. Medication profiles should be reviewed for proper dose adjustment while renal supportive care is provided. Many drugs used in ICU have been associated with prolongation of the QT interval (Table 15–4). Amiodarone and methadone are the 2 most frequently reported drugs to cause prolonged QT interval and torsades de pointes based on the data from the Food and Drug Administration (FDA) Adverse Event Reporting System (January 2004 to December 2007). Patients receive concurrent medications with QT prolongation potential should be

TABLE 15–4 Medications associated with prolonged QT interval^a in ICUs (not all inclusive).

Analgesics—Methadone
Antiarrhythmic agents Amiodarone Dofetilide Ibutilide Procainamide Quinidine Sotalol
Anesthetics Inhaled—Halothane, Enflurane, Isoflurane, Sevoflurane Intravenous—Thiopental
Antidepressants Tricyclics—Imipramine, etc SSRIs ^b —Citalopram, Fluoxetine, Venlafaxine
Antimicrobial agents Fluoroquinolones—Levofloxacin > Moxifloxacin > Ciprofloxacin Macrolides—Erythromycin (esp. high-dose IV) > Clarithromycin > Azithromycin Azole antifungals ^c —(Ketoconazole, Itraconazole) > voriconazole > Fluconazole
Antipsychotics Butyrophenones—Droperidol, Haloperidol Clozapine Olanzapine Phenothiazines—Thioridazine, etc Quetiapine Risperidone Ziprasidone
Antiemetics 5-HT ₃ antagonists—Dolasetron > Ondansetron Droperidol
Neuromuscular blocking and reversal agents Succinylcholine Atropine, Glycopyrrolate, Neostigmine

^aRisk is increased with higher dose or repeated doses in short period of time; risk is also increased in drug overdose.

^bSSRIs: selective serotonin reuptake inhibitors.

^cAzoles usually cause prolonged QT interval through interaction with another agent with QT prolongation potential.

monitored properly. Clinical decisions about drug discontinuation should be made based on the extent of QT prolongation. The risk of developing torsades de pointes is significantly increased in patients with QT intervals of greater than 500 msec.

Drug-Drug Interactions

Drug-drug interactions (DDIs) are major contributors to ADEs but can easily be prevented or managed when identified in advance. It has been estimated that at least 11% of patients admitted to a general ICU may experience DDIs. Polypharmacy, altered organ function, and advanced age are risk factors identified. DDIs may contribute to adverse events and compromise patient care with increased morbidity, mortality, and health care cost. Most DDIs can be classified as PK or PD interactions. A PK interaction occurs when one drug alters the absorption, distribution, metabolism, or elimination of another agent. A PD interaction occurs when one agent enhances or antagonizes the pharmacologic action of another agent. Antibiotics and antithrombotic agents have frequently been implicated in DDIs. Drugs that are potent inhibitors or inducers of liver cytochrome P-450 enzyme system should be used with caution. Among many of the P-450 isoenzymes identified, CYP3A4 is involved in liver metabolism of up to 50% of medications. Protease inhibitors (ie, ritonavir), macrolides (ie, erythromycin), and triazoles (ie, fluconazole, posaconazole, voriconazole) are potent CYP3A4 inhibitors. Serious DDIs with significant toxicity may develop if any of these agents is initiated concurrently with a drug that is also a CYP3A4 substrate (ie, amiodarone, cyclosporine, tacrolimus, HMG-CoA reductase inhibitors). Warfarin, an agent with narrow therapeutic index, is metabolized by several CYP enzymes, especially CYP1A2, 2C9, 2C19, and 3A4. Rifampin, a potent inducer of CYP2C9, can result in decreased warfarin effect while CYP2C9 inhibitors (ie, amiodarone, sulfonamides, voriconazole, and metronidazole) can increase the effect of warfarin. Alternative medications with minimal or no DDI should always be considered. If this approach is not possible, most of the DDIs encountered clinically can be monitored with careful dosing adjustment. A multidisciplinary team approach, especially with the presence of a clinical pharmacist on rounds, may facilitate the detection, prevention, and resolution of potential DDIs. Potential DDIs should be evaluated at the time a medication is initiated or discontinued, especially if a high-risk medication (Table 15–5) is involved.

TABLE 15–5 High-risk medications for potential drug-drug interactions in ICUs (not all inclusive).

Medications	Comments
Antiepileptics Barbiturates Carbamazepine Phenytoin* Valproic acid	Valproic acid is a P-450 enzyme system inhibitor, barbiturates, carbamazepine and phenytoin are P-450 enzyme system inducers; *Decrease GI absorption of phenytoin with concurrent enteral nutrition—may be overcome by using higher dose.
Antithrombotic agents Heparin, unfractionated Low-molecular-weight heparins Warfarin*	Interact with any agent that can affect hematologic system and hemostasis, such as antibiotics, antiplatelets. *Warfarin is highly plasma protein bound (PPB—99%) and can be displaced by other high PPB agents.
Cardiac medications Amiodarone Calcium channel blockers Diltiazem Nicardipine Verapamil Digoxin	Amiodarone and calcium channel blockers interact with each other and many drugs that rely on P-450 enzyme system for clearance. Serum digoxin level may be doubled or tripled with concurrent amiodarone, Cardizem, and verapamil administration—if combination is crucial, reduce digoxin maintenance dose by 35%-50% after regular loading dose.
CNS depressants Benzodiazepines, opioids, propofol	Synergistic sedative effect, goal-directed sedation with daily wake-up assessment if feasible to avoid excessive sedation.
Fluoroquinolones Ciprofloxacin Levofloxacin Moxifloxacin	GI absorption is impaired by concurrent polyvalent cations, such as Zn, Fe, Al, Mg; cause prolonged QT interval—potentiate other drugs that cause prolonged QT.
GI medications Proton pump inhibitors H₂-blockers	Increased gastric pH results in decreased GI absorption of certain HIV regimens, itraconazole, ketoconazole, and iron supplement.
HIV antiretroviral regimens	Ritonavir-boosted regimens: many inhibit P-450 enzyme system. Atazanavir, nelfonavir, and rilpivirine: GI absorption is reduced with stress ulcer prophylaxis.
Immunosuppressive regimens Cyclosporine Tacrolimus Sirolimus	Many interactions with medications that inhibit or induce P-450 enzyme system.
Triazole antifungals Itraconazole* Ketoconazole* Voriconazole	Many interactions via potent inhibition of P-450 enzyme system; cause prolonged QT interval—potentiate other drugs that cause prolonged QT. *GI absorption is gastric pH dependent.
Macrolides: Azithromycin Clarithromycin Erythromycin	Cause prolonged QT interval—potentiate other drugs that cause prolonged QT; inhibit P-450 enzyme system; erythromycin is the most potent inhibitor.
Nephrotoxic agents Acyclovir, Aminoglycosides, Amphotericin b, Cidofovir, Cotrimoxazole, Foscarnet, Tenofovir, etc	Close monitoring of renal function is essential—concurrent administration of these drugs need clear risk and benefit assessment; acute renal failure can also lead to excessive dosing or toxicity from other renally eliminated medications.

Medication Errors and Prevention

Medication errors (MEs) are a reality of medicine.¹⁸⁻²⁰ Harmful MEs are reported more frequently in the ICU than in the non-ICU setting. Although ME data are generally underreported, it has been estimated, that critically ill patients experience an average of 1.7 MEs per day, and many patients suffer a potential life-threatening ME during their ICU stay. Reduction of MEs is the focus of many hospital quality improvement programs. Several interventions have been shown to decrease MEs in the ICU. Improved medication safety can be accomplished by medication standardization (prophylaxis for venous thromboembolism and stress ulcer, standardized IV concentrations, etc.) computerized physician order entry, barcode technology, smart intravenous infusion devices, and medication reconciliation programs. “Medication reconciliation” has been incorporated into National Patient Safety Goal #3 as of July 2011. Patient’s complete medication regimen should be reviewed at the time of ICU admission and transfer, and should be compared with the regimen being considered for the new setting of care. This process is to ensure consistencies in medication regimens and prevent possible harms from unintentional medication omissions or therapeutic duplicates. Elimination of situational risk factors, such as inadequate trainee supervision, excessive nurse and physician work hours or work load, and distractions from the work flow, can prevent MEs. In addition, multidisciplinary team approach with physicians, physician assistants, nurses, and pharmacists is essential to medication oversight and error interception.

CLINICAL PEARLS FOR CRITICAL CARE PHARMACOLOGY

- 1) Apply pharmacokinetic and pharmacodynamic knowledge to determine the best dosing approach for critically ill patients with rapidly changing multiorgan dysfunction.
- 2) Loading dose is required to achieve desired therapeutic response timely, especially for drugs with long $T_{1/2}$. Critically ill patients must receive adequate loading dose as indicated.

- 3) Loading (initial) dose is determined mainly by the volume of distribution – no dose adjustment is required in the presence of organ dysfunction.
- 4) Maintenance doses should be adjusted based on the extent and trend of organ dysfunction, as well as the clinical indication for the therapy—lower doses may be needed if organ function continues to deteriorate whereas higher doses may be indicated in the recovery phase of organ dysfunction.
- 5) Be proactive to avoid improper dosing for patients with rapidly changing organ function—look at the trend to maximize therapeutic effect while minimizing toxicity.
- 6) Prevent medication errors and adverse drug-drug interactions—review medication profiles when high-risk drugs with known toxicity or drug-drug interactions are initiated or discontinued.
- 7) Multidisciplinary team work is the key for safe and effective pharmacologic management.

Analgesia, Sedation, and Neuromuscular Blockade

Erik Stoltenberg, MD and Aaron M Joffe, DO, FCCM

KEY POINTS

- 1 Older paradigms of analgesia and sedation in the intensive care unit (ICU) have evolved to incorporate patient-centered outcomes, such as quality of life and functional status after ICU discharge in survivors.
- 2 Techniques for appropriate pain management must be individualized to each patient, starting with an appropriate assessment of its severity. Based upon their psychometric properties (reliability and validity), the Critical Care Pain Observation Tool and Behavioral Pain Scale are currently recommended for use in adults over other reported scales.
- 3 Systemic opioids (fentanyl, morphine, and hydromorphone) are traditionally the cornerstone of postoperative and critical care pain management. The ideal method of opioid administration will vary considerably with the clinical context and include opioids by mouth or parenteral administration either via intermittent intravenous or via patient-controlled infusion pumps.
- 4 Regional analgesia should be considered in certain ICU scenarios: (1) thoracic epidural analgesia in open abdominal aortic aneurysm surgery and (2) thoracic epidural analgesia in traumatic rib fractures, especially in the elderly.
- 5 Compared with propofol and dexmedetomidine, benzodiazepines (midazolam and lorazepam) have significantly longer context-sensitive half-times at both short- and long-duration infusions. Caution should be used when using benzodiazepines in the elderly, both because these agents can cause paradoxical agitation and because altered pharmacokinetic factors, such as increased volume of distribution and decreased elimination half-life often increase time to awakening.
- 6 The depth of sedation should be routinely monitored and quantified using a validated assessment tool. Sedative medications should be titrated to keep patients continuously lightly sedated unless a contraindication exists (severe acute respiratory distress syndrome [ARDS], refractory intracranial hypertension, status asthmaticus, or epilepticus) appears noninferior to standard therapy with daily sedative interruptions.
- 7 Neuromuscular blocking agents (cisatracurium) may still play an important role in management of critically ill patients in well-defined situations including to facilitate tracheal intubation, minimize systemic oxygen consumption in the setting of severe and refractory hypoxemia, improve outcomes in moderate and severe ARDS, treat shivering in patients undergoing targeted temperature management therapy, or treat refractory intracranial hypertension.

In addition to providing vital organ support and treatment of the underlying condition responsible for admission to the intensive care unit (ICU), the health care team must assure patient comfort and limitation of further stress on the patient. Failure in this regard may result in physiologic derangement and unwanted cognitive side effects. In order to attain these goals, a thorough knowledge of the pharmacokinetics (what the body does to the drug) and pharmacodynamics (what the drug does to the body) of a variety of medications is necessary; many of these agents are used exclusively in the ICU or by anesthesiologists in the operating room.

Over the past decade, an expanding body of basic science and clinical research has changed the way intensivists think about the treatment of pain and the management of sedation in the ICU. The use of newer drugs, such as dexmedetomidine as well as newfound indications for older drugs (eg, ketamine and lidocaine), have improved our ability to provide appropriate analgesia and sedation in the ICU. Recent trial results have provided high-quality evidence for use of neuromuscular blockade, despite its side-effect profile, in specific clinical circumstances (eg, severe acute respiratory distress syndrome [ARDS]). Older paradigms of analgesia and sedation in the ICU have evolved to incorporate patient-centered outcomes, such as quality of life and functional status after ICU discharge in survivors. This has been accomplished by aggressive assessment and treatment of patient discomfort and focusing on maintaining the ability of the patient to interact with caregivers and their environment through lighter sedation. The goals of this chapter are to underscore the necessity of analgesia and sedation in the ICU; describe pharmacologic properties of important analgesics, sedatives, and neuromuscular blocking drugs (NMBDs); and describe clinical strategies that improve patient outcomes.

ANALGESIA

Epidemiology of Pain in the ICU

Pain is common in the ICU, but is more difficult to assess than in acute care patients because of a common inability for critically ill patients to subjectively

express pain. The inherent subjective nature of pain is well described by the International Association for the Study of Pain, which defines pain as an “unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.”¹ However, the inability to communicate pain does not mean it is not being experienced by the patient. In fact, it has been reported that the majority of critically ill patients (both medical and surgical) do experience pain^{1,2}—which patients describe as a significant source of stress, if not the most significant source of stress during their ICU stay, even when asked 6 months later.³

In addition to an unpleasant experience, undertreated pain may have negative somatic and long-term consequences. The pain response increases plasma catecholamine levels, causing vasoconstriction, impaired tissue oxygenation, and increased myocardial oxygen demand. Pain can cause neuroendocrine activation resulting in a catabolism state, breakdown of muscle tissue, and impaired immune function, which can increase susceptibility to infection. In addition to acute anxiety and fear, acute pain is associated with chronic pain, posttraumatic stress disorder, and lower health-adjusted quality of life after ICU discharge.

Physiology and Anatomy of Pain

The pleiotropic effects of pain are due to the complicated processing of pain from stimulus to cerebral cortex. There are four described elements of pain processing:

- 1) Transduction. Noxious stimuli are converted to an action potential.
- 2) Transmission. Action potentials are conducted via afferent neurons.
- 3) Modulation. Afferent pain signals are altered by efferent neural inhibition via neurotransmitters, especially in the dorsal horn of the spinal cord or by augmentation via neuronal plasticity (eg, central sensitization).
- 4) Perception. Integration of afferent pain signals in the cerebral cortex.

Specific analgesic drugs and drug classes, which act at each of these four pathways, are presented in [Table 16–1](#). Multimodal analgesic strategies are those

TABLE 16–1 Specific analgesic drug classes and how pain signals are modulated.

Transduction	Transmission	Modulation	Perception
NSAIDs	Local anesthetics:	Spinal opioids	Parenteral opioids
Antihistamines	Peripheral nerve blocks	α_2 -Agonists	α_2 -Agonists
Membrane stabilizing agents	Epidural analgesia	NMDA receptor antagonists (ketamine)	Inhaled anesthetics
Opioids		NSAIDs	
Bradykinin and serotonin antagonists		CCK antagonists	
Topical anesthetics		K ⁺ channel openers	
		NO inhibitors	

NSAIDs, nonsteroid anti-inflammatory drugs; NMDA, N-methyl-d-aspartate; CCK, cholecystokinin.

considered to target more than one pathway simultaneously. Pain chronicization—a transition from acute pain to chronic pain—is a feared consequence of painful critical illness, and much research has addressed neuronal plasticity in this pathophysiology. Fortunately, therapeutic options have been developed to decrease the risk of this transition, and will be discussed further as follows (see Nonopioid Analgesics).

Strategies for Pain Management

Assessment of Pain

Techniques for appropriate pain management must be individualized to each patient, starting with an appropriate assessment of its severity. This assessment should be more detailed than a simple visual analog scale (VAS). If the patient is able to adequately communicate pain, the following should be assessed: site, onset and timing, quality, severity, exacerbating and relieving factors, response to analgesics, and assessment of pain with movement, breathing, and cough.

As mentioned earlier, critically ill patients may not be able to self-report, so behavioral assessments should be used. Based upon their psychometric properties (ie, reliability and validity), the Critical Care Pain Observation Tool and Behavioral Pain Scale are currently recommended for use in adults over other reported scales. It should also be noted that the use of vital signs as the sole surrogate for pain is strongly discouraged. Although more

validation testing in certain patient populations who may fail to exhibit typical pain behaviors (eg, neurologically injured) is warranted, implementation of behavioral scales is associated with lower resource consumption—such as days of mechanical ventilation—and ICU length of stay (LOS).³

Opioids—Systemic opioids are traditionally the cornerstone of postoperative and critical care pain management. As shown in Table 16–1, opioids’ sites of action affect 3 of 4 pain-processing pathways. Opioids act as ligands at G protein-coupled opioid receptors, namely, the μ (mu), δ (delta), and κ (kappa) receptors. These receptors are located peripherally, in the spinal cord dorsal horn as well as at various locations in the brain. Opioid receptors are located on primary afferent neurons and inhibit release of nociceptive substances, decrease neurotransmitter release in the spinal cord, and activate descending inhibitory neurons. The μ -receptor is thought to be responsible for much of the peripheral analgesia caused by opioid agonists. There are a number of opioid receptor subtypes that have been discovered and are expressed on a variety of different cells, some unrelated to the central nervous system (CNS) and peripheral nervous system (such as on leukocytes and vascular tissue). This broad expression of opioid receptors is likely because there are number of endogenous opioids. The complicated interaction and broad expression of opioid receptors has led to opioids being implicated in such diverse pathophysiology as increased rates of

TABLE 16–2A Opioid analgesics (adapted from Joffe et al⁶).

Opioid	IV Dose (mg)	PO Dose (mg)	Time to Onset	Time to Peak Effect	Duration of Effect	Infusion Rate
Morphine	5	15	< 5 min (IV), 30 min (PO)	30 min (IV)	3-4 h	2-30 mg/h
Hydromorphone	0.7	4	< 5 min (IV), 30 min (PO)	30 min (IV)	4-5 h	0.5-3 mg/h
Fentanyl	0.05	N/A	Immediate	< 5 min	30-60 min	25-300+ mcg/h
Remifentanyl	N/A	N/A	Immediate	< 3 min	< 10 min	0.05-0.3 mcg/kg/h
Oxycodone	N/A	10	20-30 min	< 1h	3-4 h	N/A
Methadone		(variable)	10-20 min (IV), 30 min (PO)	10-20 min (IV), 30-60 min (PO)	3-6 h (longer with repeat dosing)	N/A

cancer recurrence and modulation of inflammation. Intensivists should, therefore, have an appreciation not only for the acute adverse effects of opioids (respiratory depression and sedation), but also more subtle, long-term effects of opioid therapy. For more information regarding specific opioids, see [Table 16–2a](#) and [16–2b](#).

The ideal method of opioid administration will vary considerably with the clinical context and include opioids by mouth or parenteral

administration either via intermittent intravenous or via patient-controlled infusion pumps (PCA, patient-controlled analgesia). For patients requiring mechanical ventilation, bolus or continuous infusion of opioids can treat both pain and ventilator-associated anxiety.

PCA—For awake, alert patients with moderate to severe pain—most commonly postoperative patients—PCA is an appropriate choice. Before initiating a PCA order, the patient must be able to

TABLE 16–2B Opioid analgesics (adapted from Joffe et al⁶).

Opioid	Elimination Half-Life	Metabolic Pathway	Active Metabolites	Notes
Morphine	1.5-2 h	Liver: glucuronidation	Morphine 6- and 3-glucuronide	Histamine release may be important from a cardiovascular and pulmonary perspective. Caution in renal failure.
Hydromorphone	2-3 h	Liver: glucuronidation	None	Accumulation with hepatic dysfunction.
Fentanyl	3-4 h	Liver: N-dealkylation CYP3A4/5	None	Significant increase in context-sensitive half-time with infusions >12 h.
Remifentanyl	10-20 min	Plasma esterase hydrolysis	None	Abrupt discontinuation of analgesia.
Oxycodone	3-4 h	Liver: CYP2D6	Noroxycodone and oxymorphone	
Methadone	8-59 h	Liver: N-methylation CYP3A4, 2D6	none	NMDA receptor-antagonist, unpredictable pharmacokinetics (risk for accumulation). Multiple drug–drug interactions. Can prolong QTc.

NMDA, N-methyl-d-aspartate.

understand how to appropriately use the PCA apparatus. To determine the PCA prescription, the following parameters must be specified: (1) opioid, (2) incremental (or demand) dose, (3) lockout interval, (4) background infusion rate (if any), (5) 1- and 4-hour dose limits, and (6) bolus dose administration (for breakthrough pain). A reasonable starting prescription in an opioid-naïve patient would be morphine with an incremental dose of 1 to 2 mg, a lockout of 6 to 10 min, no continuous infusion rate, a 4-hour maximum dose of 30 mg, and a bolus dose of 2 to 4 mg every 5 min for 5 doses.

Although PCA has gained significant popularity for its ease of use, when compared to intermittent bolus opioids, outcome studies show mixed results. There is some evidence that patient satisfaction is improved, possibly because of the patients' increased sense of control over pain.⁴ In general, there seems to be little change in analgesic efficacy, with patients reporting similar VAS pain scores with PCA and intermittent IV bolus analgesia. For patients that are taking chronic opioids when treated with a PCA, total dose of opioid was thrice higher than patients not taking opioids previously.⁵ Interestingly, patients with opioid tolerance had increased rates of sedation compared with opioid-naïve patients, which suggests the therapeutic index for opioid-tolerant patients may be narrower than opioid-naïve patients.

Nonopioid Analgesics

Acetaminophen and Nonsteroidal Anti-inflammatory Drugs

Acetaminophen is a ubiquitous centrally acting cyclooxygenase inhibitor with a long history of use outside the ICU, but very little research has been applied to critically ill patients. Much of the research in non-ICU patients showed modest (but statistically significant) reductions in mild and moderate pain. The notable exception regards research studying the IV formulation of acetaminophen, which became available in the United States in early 2011. Pharmacokinetic studies showed increased plasma and cerebrospinal fluid levels of acetaminophen after IV administration compared with oral or rectal administration. Although studies results are mixed, decreased VAS pain scores, opioid side effects, and early extubation following major surgery have all been demonstrated with IV

acetaminophen.⁶ Given the common scenario of treating patients in the ICU with moderate to severe pain and concern for impaired absorption from the gastrointestinal tract or when side effects of opioids are particularly harmful, IV acetaminophen may play an important role, but attention should be paid to the increased cost of the IV formulation.

Many acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are used in acute postoperative pain and pain associated with critical illness; these drugs work primarily through cyclooxygenase and prostaglandin synthesis inhibition. All are generally effective in decreasing moderate and severe pain in equal-analgesic doses, but their utility is limited by their side effect profiles. NSAIDs can indirectly cause constriction of the afferent renal arterioles and inhibit platelet function (both in clinically significant ways), so their use is relatively contraindicated in patients at risk for renal injury and significant bleeding.

Ketamine

Ketamine, historically used as an IV dissociative general anesthetic with hypnotic and analgesic properties, has been the subject of much research in the treatment of acute pain. Ketamine acts primarily through N-methyl-d-aspartate (NMDA) receptor antagonism, which plays an important role in pain modulation and prevention of the transition of acute pain to chronic pain. Prevention of pain chronicization is a particularly useful characteristic of ketamine, especially in those patients that are opioid tolerant, as evidenced by a randomized controlled trial (RCT) of patients undergoing spine surgery that showed reductions in pain scores at 48 hours and 6 weeks after ketamine versus placebo infusion intraoperatively.⁷ Ketamine also may reduce opioid-related side effects, including nausea and vomiting. Because analgesic adjunct doses of ketamine (0.05-0.4 mg/kg/h) are significantly smaller than anesthetic doses (1-3 mg/kg/h), psychomimetic reactions from ketamine are significantly less common at these doses, and only slightly more common than placebo. Other side effects of ketamine (sympathetic stimulation and salivation) are not usually observed with analgesic doses.

Lidocaine

Lidocaine is a well-known sodium channel antagonist local anesthetic that also has antiarrhythmic,

general anesthetic, and analgesic (both antinociceptive and antineuropathic) properties. It has been studied extensively in the perioperative setting as an IV infusion, with mainly mixed results. Cytokine levels decrease after lidocaine infusion, suggesting that inflammation causing nociceptive pain may be decreased. Lidocaine has also been shown to modestly decrease VAS scores, opioid requirements, and duration of postoperative ileus postoperatively.⁶ A recent study enrolling patients with complex spine surgery showed a significant improvement in subjective physical health months after surgery with lidocaine infusion versus placebo (a secondary outcome measure).⁸ Lidocaine has significant cardiac toxicity and is cleared by the liver, and therefore, should be used with caution in critically ill patients with hepatic dysfunction.

Gabapentin and Pregabalin

As with lidocaine and ketamine, the calcium channel blockers gabapentin and pregabalin have been useful in treating neuropathic pain. There is considerable research demonstrating increased analgesic

efficacy of gabapentin as part of a regimen that also includes opioids in patients with chronic pain. There is also evidence for effectiveness in reducing opioid requirements and opioid-related side effects in patients with acute postoperative pain. Data supporting use of gabapentin and pregabalin in the ICU is limited, but a study evaluating patients with pain related to Guillain-Barre demonstrated decreased pain scores and opioid consumption in the ICU compared with placebo. In a meta-analysis of postoperative patients (not necessarily in the ICU) the number-needed-to-treat-to-benefit (NNT) to achieve 50% reduction in pain for gabapentin (NNT 11) is higher than that of naproxen (2.7), ibuprofen (2.5-2.7), or oral oxycodone 15 mg (4.6).^{1,9-12} The most common side effect of gabapentin is sedation, but this effect is relatively rare—number needed to harm was 35.^{7,13} Taken together, these data suggest gabapentin and pregabalin are safe and effective adjuncts in the treatment of pain in the ICU.

A summary of nonopioid analgesics is provided in [Table 16–3](#).

TABLE 16–3 Nonopioid analgesics.

Drug	IV or PO Dose	Half-Life	Metabolism	Notes
Ketamine	IV: 0.1-0.5 mg/kg bolus, then 0.05-0.4 mg/kg/h	2-3 h	CYP450: 2B6, 2C9, 3A4, urinary excretion	Attenuates opioid-induced hyperalgesia, may decrease persistent postoperative pain
Acetaminophen	IV/PO: 650-1000 mg q4-6 h (<4000 mg per day)	2-4 h	CYP450: 1A2, 2E1, urinary excretion	Use caution in hepatic impairment
Ketorolac	IV: 15-30 mg q6 h up to 5 days	2.4-8.6 h	CYP450. Less than 50% metabolized. 90% excreted in the urine, 6% in bile/feces	Avoid use in patients with aspirin allergy. Caution with renal dysfunction, patients at high risk for bleeding, and in elderly patients.
Ibuprofen	PO: 400 mg q 4 h	1.8-2.5 h	CYP450: 2C9, urinary excretion	Same caution as with ketorolac, IV formulation also available.
Gabapentin	PO: 100 mg TID, can titrate up to maximum dose 1800 mg/day	5-7 h	Minimal. Excreted intact in urine.	May cause sedation. Abrupt discontinuation may cause seizures.
Pregabalin	PO: 50 mg TID, may increase to 100 mg TID	5.5-6.7 h	Minimal metabolism (2%). Renally excreted.	
Lidocaine	IV: 1.5 mg/kg loading dose, 1-2 mg/kg/h	1.5-2 h	Hepatic CYP450 (1A2 and 3A4), 10% unchanged in the urine	Active metabolites may accumulate in hepatic or renal failure

Regional Analgesia and Nonpharmacologic Techniques

Regional analgesia—targeted administration of local anesthetics and analgesics to certain anatomic locations—may have considerable advantage in the management in acute postsurgical and traumatic pain. Lower doses of medication can be delivered in a targeted fashion to decrease the risk of side effects of systemic delivery of medication, and analgesia is often significantly improved compared to IV opioids. In certain ICU scenarios regional analgesia should be considered: (1) thoracic epidural analgesia in open abdominal aortic aneurysm surgery and (2) thoracic epidural analgesia in traumatic rib fractures, especially in the elderly. Using thoracic epidural analgesia in both these scenarios is supported by clinical practice guidelines from the Society of Critical Care Medicine,³ and have improved clinical outcomes—mainly by decreasing respiratory complications.

Although data supporting regional analgesia as a means to reduce morbidity is limited, in a broader array of scenarios regional analgesia decreases VAS pain scores, decreases systemic opioid requirements, decreases opioid side effects (postoperative ileus and urinary retention), and it may improve patient satisfaction.⁶ In a recent meta-analysis, regional anesthesia decreased the incidence of persistent postoperative pain 6 months postsurgery after thoracotomy and breast surgery by two-thirds (odds ratio = 0.33, 95% confidence interval [CI]: 0.2–0.66).¹⁴

In addition to pharmacologic analgesic therapy, there are a variety of nonpharmacological analgesic techniques that may be helpful to patients. These techniques include music therapy, relaxation, therapy, family presence, distraction, massage, and deep breathing. Although empiric evidence of their efficacy is mixed and precludes high-level recommendations, their low cost and safety make them a valuable consideration within the context of a multimodal analgesia strategy in the ICU.

SEDATION

Sedation Pharmacology

Once determining that sedation is necessary for a critically ill patient, the selection of sedative should be based on the predicted length of required

sedation, the reason sedation is necessary (eg, agitation, increased intracranial pressure, or alcohol withdrawal) as well as the pharmacodynamics and pharmacokinetics of the drug (Table 16–4). This strategy should involve patient factors, such as hepatic and renal dysfunction, hemodynamic stability, and inferred changes in drug volume of distribution (V_D).

Critical illness can significantly alter sedative pharmacokinetics in a variety of ways. Most sedatives undergo hepatic metabolism, many with a high hepatic extraction ratio, and therefore, decrease in hepatic blood flow that occur commonly in patients with shock, after abdominal surgery, or with increased intra-abdominal pressure can significantly decrease drug clearance. Sedatives are often significantly bound to plasma proteins, and therefore, decrease in plasma protein concentration can increase the concentration of drug in the CNS. Perhaps the most important pharmacokinetic principle with respect to sedative infusions is the context-sensitive half-time, which is a calculated multicompartiment model-derived graph of the time required for a 50% reduction in drug concentration at the effect site versus infusion duration for a constant-rate infusion. Some drugs (propofol) have a short half-time if the infusion is relatively short-lived (hours), but the half-time may increase significantly if the infusion is continued for days. The main difference in context-sensitive half-times between sedatives is the rate at which the half-times increase with infusion time. Compared with propofol and dexmedetomidine, benzodiazepines have significantly longer context-sensitive half-times at both short and long duration infusions—an important fact to consider when choosing a sedative.

Propofol

Propofol is a commonly used IV anesthetic induction agent that has excellent effectiveness in the ICU for varying levels of sedation. It works on a variety of CNS receptors to block neural transmission, including gamma-aminobutyric acid (GABA), and not only cause sedation, hypnosis, and amnesia, but also has anticonvulsant and antiemetic properties. It has no analgesic properties. It is highly lipid soluble and therefore crosses the blood-brain barrier and redistributes to vessel-poor compartments quickly,

TABLE 16–4 Sedating medications.

Drug	IV Loading Dose	Infusion Rate	Time to Onset	Elimination Half-Life*	Active Metabolites	Notes
Midazolam	0.01-0.05 mg/kg	0.02-0.1 mg/kg/h	2-5 min	1.7-2.6 h	Yes (α -hydroxy-midazolam and conjugated α -hydroxy-midazolam)	Active metabolites especially important in renal failure; adverse effects—hypotension, respiratory depression
Lorazepam	0.02-0.04 mg/kg	0.01-0.1 mg/kg/h	15-20 min	11-22 h	No	Propylene glycol (carrier solution) can cause acidosis; adverse effects—hypotension, respiratory depression
Propofol	0.1-0.3 mg/kg	5-50 μ g/kg/min	1-3 min	4-23 h	No	Soybean oil and lecithin carrier (avoid with egg allergy) Adverse effects: hypotension, respiratory depression, propofol-related infusion syndrome, pain on injection, hypertriglyceridemia, pancreatitis
Dexmedetomidine	1 μ g/kg over 10 min	0.2-0.7 μ g/kg/h	5-10 min	1.8-3.1 h	No	Adverse effects—bradycardia and hypotension, hypertension with loading dose; difficult to achieve deep sedation

*For short-term infusions. Half-lives can be significantly longer after longer infusions given context-sensitive half-time (see text). Adapted with permission from Barr J, Fraser GL, Puntillo K, et al: Clinical practice guidelines for the management of pain, agitation, and delirium in adult patients in the intensive care unit, Crit Care Med 2013 Jan;41(1):263-306.

resulting in a fast-onset, fast-recovery when given in bolus doses and short infusions. It is, therefore, useful in spontaneous awakening trial (SAT) protocols (see “the case of lighter sedation” later) and in patients that require frequent neurological assessments. Given the context-sensitive half time, delayed awakening after prolonged infusions still occurs.

The most common adverse effect with propofol is hypotension caused by arterial and venous vasodilation in addition to direct myocardial depression. The hemodynamic effects are dose dependent, and are less profound with infusion rates targeted to moderate sedation than with bolus induction doses. The carrier solution (lipid solution containing egg lecithin and soybean oil) is potentially allergenic and has been implicated in the rare propofol infusion syndrome—a potentially devastating severe metabolic acidosis associated with hypotension,

hypertriglyceridemia, rhabdomyolysis, ECG changes, and multiorgan dysfunction.

Dexmedetomidine

Dexmedetomidine is a potent α_2 -adrenergic receptor agonist with a potency several fold higher than clonidine (α_2 : α_1 activity = 1,620:1 and 220:1 for dexmedetomidine and clonidine, respectively). The relative densities of these receptors in the CNS account for the sedative, sympatholytic, and analgesic properties of the drug. Dexmedetomidine usually results in a lightly sedated, interactive, cooperative patient. Because of minimal respiratory depression, it is particularly useful in facilitation of liberation from mechanical ventilation and extubation, as an infusion can be safely continued during a spontaneous breathing trial through extubation. Although it is only Food and

Drug Administration (FDA)-approved for ICU sedation at doses up to 0.7 $\mu\text{g/kg/h}$ for 24 hours, there is empiric evidence to support safety at higher doses (1.5 $\mu\text{g/kg/h}$) for longer durations (up to 28 days).

Concerns with dexmedetomidine are primarily hemodynamic, as it can cause hypotension at rates similar to that of propofol. Loading doses of dexmedetomidine delivered too rapidly can cause severe life-threatening hypertension and bradycardia. Hypertension is likely caused by agonism of the peripheral α_1 or α_{2B} receptor subtype in the periphery resulting in vasoconstriction. Because of sympatholysis seen with continuous infusion, attempts to achieve deeper levels of sedation may be limited by bradycardia and hypotension. Lastly, it should be noted that the dosing of dexmedetomidine is unique among standard critical care infusions owing to its potency— $\mu\text{g/kg/h}$ and not $\mu\text{g/kg/min}$.

Benzodiazepines

Benzodiazepines provide anxiolysis, sedation, hypnosis, and anticonvulsant effects through activation of GABA_A receptors in the brain. The most common benzodiazepines used in the ICU are midazolam and lorazepam, because they can be used effectively both as intermittent boluses and as infusions. However, the context-sensitive half-times of benzodiazepines are significantly longer than that of propofol or dexmedetomidine, and therefore, benzodiazepines may cause residual sedation hours to days after infusions are stopped. Because of hepatic metabolism, benzodiazepine clearance may be reduced in patients with hepatic dysfunction or when coadministered with cytochrome P₄₅₀ inhibitors.

Although midazolam has a shorter elimination half-life than other benzodiazepines, there is greater variability and potentially longer time to awakening with midazolam, likely secondary to accumulation of an active metabolite (conjugated and unconjugated α -hydroxymidazolam). This accumulation is especially important with concomitant renal dysfunction. Caution should be used in the elderly, both because benzodiazepines can cause paradoxical agitation and because altered pharmacokinetic factors such as increased volume of distribution and decreased elimination half-life often increase time to awakening.

Historical Context of Sedation for Mechanical Ventilation

Because the widespread implementation of positive pressure ventilation, use of sedatives to ensure patient-ventilator synchrony has been a mainstay of the practice of critical care. In the early days of mechanical ventilation, synchronized patient-ventilator interaction was very difficult or impossible, and was thought to require deep sedation to ensure optimal respiratory physiology. The patient experience of ICU care was considered to be inhumane and the provision of deep sedation was felt to provide comfort and amnesia to the experience. Treatment of ARDS involved normalizing respiratory physiology and gas exchange, which often involved deep sedation and comatose patients. In general, protocols to systematically assess the depth of sedation were not used. High infusion rates of intermediate-acting benzodiazepines and opioids were common, and patients were often unresponsive for days at a time. Although it is now apparent that this sedation paradigm directly contributes to worse outcomes, change in clinical practice has been slow. Even after a number of studies suggested that deep sedation may be harmful, 40% to 50% of patients were observed to be deeply sedated.¹⁵ Finally, strategies of ICU sedation have changed considerably; the evidence for these changes will be discussed here. As follows, the reader will find summaries of seminal works that have greatly informed current sedation paradigms, but are strongly encouraged to perform a more in-depth reading of the primary source material.

The Case for Lighter Sedation

Observations from more than 20 years ago noted that mechanically ventilated ICU patients sedated by continuous infusion had significantly longer duration of mechanical ventilation, ICU, and hospital lengths of stay than those who were sedated by intermittent intravenous boluses.¹⁶ Likely as a result, rates of documented ventilator-associated pneumonia (VAP) were also higher. In response, Kress and colleagues performed a trial comparing a protocol of daily sedative interruption (DSI, now referred to as SAT) to sedation as directed by the physician.¹⁷ About 150 patients were enrolled in the study at a single center, and the duration of

mechanical ventilation, hospital LOS and ICU LOS were the primary endpoints. Duration of mechanical ventilation and ICU LOS were both decreased in the DSI group by 2.4 days (4.9 days, 95% CI: 2.5-8.6 vs 7.3 days, 95% CI: 3.4-16.1, $P = 0.004$) and 3.5 days (6.4 days, 95% CI: 3.9-12 vs 9.9 days 95% CI: 4.7-17.9, $P = 0.02$), respectively. There was no difference in rates of self-extubation or mortality. The authors concluded, “daily interruption of sedation is a safe and practical approach to treating patients who are receiving mechanical ventilation.”

Recognizing the results of this trial and appreciating the intertwined nature of mechanical ventilation and sedation, Girard et al published a multicenter study combining protocols of SATs (after a SAT safety screen) with spontaneous breathing trials (SBTs) and compared the protocol with usual care.¹⁸ The so-called “Awakening and Breathing Controlled Trial” (ABC trial) enrolled 336 patients in 4 centers with a primary outcome of time breathing without assistance during the first 28 days after enrollment. Not only did the protocol patients have an increased mean/median number of ventilator-free days of 14.7/20 versus 11.6/8.1 ($P = 0.02$ for mean), but secondary outcomes of 1 year mortality were significantly decreased in the protocol patients (44% vs 58%, $P = 0.01$). It is important to note that the rate of self-extubation was higher in the intervention group, but the rate of reintubation was not different.

Both the Kress et al trial and ABC trial had a control group with usual care, which usually consisted of sedation that was not interrupted. Although the Kress et al trial targeted sedation depth in both groups to achieve a score of 3 or 4 on the Ramsay sedation scale (3—responsive to commands and 4—asleep with a brisk response to a light glabellar tap or loud sound), patients in the control arm were only “awake” (responsive to commands) on 9% of patient-days. In the ABC trial, both control and intervention group had sedation that was titrated to different institution-specific endpoints. However, the control group had an increased duration of coma during the study period (3 days, IQR 1-7 vs 2 days, IQR 0-4, $P = 0.002$). Given these data, both control group patients were comatose for a significantly greater amount of time than the intervention group patients. An important question remained—would

a SAT/SBT be superior to a strategy that simply titrated sedation to a lighter, noncomatose, level?

A multicenter trial attempted to answer this question by randomizing 430 patients to one of two protocols: (1) protocolized sedation targeting a RASS of -3 to 0 (sedated but opening eyes to voice [-3] to alert and calm [0]) plus daily sedation interruption or 2) protocolized sedation (RASS -3 to 0) alone without interruption of sedating medications.¹⁹ The primary outcome measure was time to successful extubation. There was no difference in time to successful extubation in the groups. Interestingly, secondary outcome measures showed an increase in the dose of sedating medications and the self-perceived nurse workload in the interruption group. There were no differences in self-extubation or delirium.

Given that sedation interruptions and perhaps lighter sedation improves outcomes, some ICUs have adopted a practice of no sedation for mechanical ventilation. In one such mixed medical-surgical ICU in Denmark where the nurse: patient ratio is 1:1 and extra staff are available to “verbally comfort and reassure the patient,” a RCT was performed to compare the intervention group (no sedatives) to the control group (sedation with goal Ramsay score 3-4 and daily sedation interruption).²⁰ Analgesia with as needed IV morphine was administered in both groups. The primary outcome measure was the number of days without mechanical ventilation in a 28-day period, with secondary endpoints being brain imaging (MRI or CT), accidental extubation, and VAP. The no sedation group had 4.2 days (95% CI: 0.3-8.1) more without mechanical ventilation in the 28 days after randomization (corrected for baseline variables). The secondary outcomes were not different between the groups. As assessed by the gold standard criteria, the DSM IV, more patients in the no sedation group experienced agitated delirium than in the control group (20% vs 7%, $P = 0.04$); these patients were treated with higher average doses of haloperidol, although the dose was small in both groups. This trial addressed the frequent appeals for a RCT comparing strategies of sedation versus no sedation and showed that, in carefully selected patients within a particular staffing model, sedation may contribute to prolonged mechanical ventilation and may be unnecessary. A large multicenter trial in

Denmark and Norway (NONSEDA Study Group) is attempting to confirm these findings by enrolling 700 patients using the same protocol.

From currently available data, it is now apparent that (1) depth of sedation should be routinely monitored and quantified using a validated assessment tool, (2) titrating medications to keep patients continuously lightly sedated unless a contraindication exists (severe ARDS, refractory intracranial hypertension, status asthmaticus, or epilepticus) appears noninferior to standard therapy with DSIs, (3) titration of sedation and SBTs should be closely coordinated in a multidisciplinary team that involves respiratory therapists, nurses, and the medical team.

NEUROMUSCULAR BLOCKADE

As the paradigm of ICU sedation continues to shift away from deep sedation and immobility, the list of accepted indications for use of NMBDs in mechanically ventilated patients has diminished considerably. However, NMBDs may still play an important role in management of critically ill patients in well-defined situations. These may include use to facilitate tracheal intubation, minimize systemic oxygen consumption in the setting of severe and refractory hypoxemia, improve outcomes in moderate and severe ARDS, treat shivering in patients undergoing targeted temperature management therapy, or treat refractory intracranial hypertension. Other “relative” indications, such as in protection of important vascular anastomoses (free flaps), taut wound closures and tracheal anastomoses, are dubious in nature and should be questioned. It is also important to note that administration of a NMBD excludes the use of subjective assessments of pain and sedation depth. In this setting, use of objective measures of brain function, such as bispectral index monitoring (BIS) or formal electroencephalography (EEG) to monitor depth of sedation should be considered.

NMBD Pharmacology

NMBDs have unique pharmacology that necessitates knowledge of the biochemistry of nicotinic acetylcholine receptors at the neuromuscular junction (NMJ). NMBDs are classified as either depolarizing

or nondepolarizing based on their action at the postsynaptic nicotinic acetylcholine receptor.

Succinylcholine is the only depolarizing NMBD available in the United States—it depolarizes nicotinic acetylcholine receptors and either desensitizes the receptor, inactivates sodium channels and prevents propagation of an action potential, or a combination of both. It acts similarly to acetylcholine at the receptor, but binds significantly longer, and therefore, can cause significant hyperkalemia by the resulting efflux of potassium from muscle cells, especially in the setting of extrajunctional acetylcholine receptors. These extrajunctional receptors are expressed more frequently on muscle cells that have been denervated by neurologic disease (stroke, Guillain–Barre, spinal cord injury, severe burns, and prolonged immobility), and therefore, fatal hyperkalemia can result in these cases. Succinylcholine has other important adverse effects including hypertension, tachycardia, bradycardia, ventricular arrhythmias, and less commonly, increased intracranial pressure and malignant hyperthermia.

Nondepolarizing NMBDs are competitive inhibitors of acetylcholine, and inhibit depolarization at the NMJ. Therefore, the presence of extrajunctional acetylcholine receptors is not a concern with this class of NMBDs. These NMBDs are subclassified by duration of action (short, intermediate, and long) and chemical structure (benzylisoquinoline or aminosteroid). All commonly used nondepolarizing NMBDs are intermediate acting. A summary of the pharmacology of NMBDs commonly used in the ICU is presented in [Table 16–5](#).

Neuromuscular Blockade for Facilitation of Mechanical Ventilation

NMBDs have been used to avoid patient-ventilator dyssynchrony in the setting of severe and/or refractory gas exchange abnormalities, particularly hypoxemia, but a number of case series suggest that they are associated with prolonged neuromuscular weakness. Although some of these cases were ascribed to decreased drug clearance in the setting of renal and hepatic dysfunction, some were thought to result from pathologic myopathy.²¹ This myopathy has also been demonstrated in rats after prolonged exposure to vecuronium. Many of the cases with

TABLE 16–5 Neuromuscular blocking drugs.

Drug	Use	Category	Duration of Action	Intubating Dose (RSI) (mg/kg)	Notable Pharmacology
Succinylcholine	RSI	Depolarizing	Short	1-1.5	Contraindications: denervated muscle, hyperkalemia, increased intraocular pressure, susceptibility to MH
Rocuronium	RSI	Nondepolarizing, aminosteroid	Intermediate	1.2	Variable recovery with repeated dosing, renal and hepatic clearance
Vecuronium	Induction, infusion	Nondepolarizing, aminosteroid	Intermediate	N/A	Renal and hepatic clearance
Cisatracurium	Induction, infusion, ARDS	Nondepolarizing, benzylisoquinoline	Intermediate	N/A	Hoffman degradation

potential myopathy involved aminosteroid NMBDs (see Table 16–5). Although there have been case reports of prolonged weakness after infusion of benzylisoquinoline, it is thought to be less of a concern than with aminosteroid compounds. The most commonly used benzylisoquinoline NMBD, cisatracurium, also has the advantage of being degraded by Hoffman elimination and ester hydrolysis in the plasma, and is therefore, not dependent on renal or hepatic function for clearance.

Infusion with cisatracurium for 48 hours for treatment of moderately severe and severe ARDS was recently studied in a double-blind RCT in France in 340 patients.²² The primary outcome measure (adjusted hazard ratio for death at 90 days) was 0.68 (95% CI: 0.48-0.98, P = 0.04) for the cisatracurium group, with no difference in ICU-acquired paresis. In both groups, a large number of patients were receiving corticosteroids for septic shock, which may contribute to ICU myopathy. A meta-analysis including this trial as well as two smaller studies also supports the notion that short-term use of cisatracurium reduces hospital mortality and barotrauma without an increased risk of ICU-acquired weakness. Thus, current evidence supports the short-term use of cisatracurium for severe ARDS, and should be in any intensivist’s armamentarium for treatment of severe ARDS. As mentioned previously, depth of sedation monitoring with BIS or EEG should be considered if

NMBDs are used. However, NMBD use to facilitate mechanical ventilation in patients without moderately severe to severe ARDS is strongly discouraged.

Airway Management/ The Difficult Airway

Venketraman Sahasranaman, MD; Tarang Saffi, MD;
Mabel Chung, MD and Jay Berger, MD/PhD

KEY POINTS

- 1 The anatomy of the airway starts at either the nasopharynx or oropharynx, and continues inferiorly past the larynx into the trachea.
- 2 In an emergency when the patient cannot be intubated or ventilated, the airway can be surgically entered via the cricothyroid membrane.
- 3 Difficult ventilation is a situation in which adequate ventilation cannot be achieved.
- 4 Identifying patients with potentially difficult airways is essential due to the increased incidence of complications associated with difficult intubations.
- 5 Preoxygenation increases the safety buffer time available during the peri-intubation period.
- 6 In order to insure amnesia, analgesia, and muscle relaxation during intubation, a balanced approach utilizing multiple medications are required.
- 7 Confirmation of correct placement of the endotracheal tube can be accomplished directly by visualizing the tube passing through the vocal cords or indirectly by auscultating bilateral breath sounds, observing rise and fall of the chest wall, and by capnography.
- 8 The risk of aspiration in patients with suspected or known full stomachs can be decreased by utilizing a rapid sequence intubation technique.

INTRODUCTION

The majority of patients admitted to the intensive care unit have varying degrees of respiratory failure. The intensivist must decide whether these patients would benefit from supplemental oxygen, noninvasive positive pressure ventilation (NIPPV), or endotracheal intubation with mechanical

ventilation. The ability to secure an airway with a tracheal tube is therefore a necessity for all intensivists. As can be seen in [Table 17–1](#), there are multiple indications for intubation. In this chapter, the airway management of critically ill patients will be discussed, including the preintubation assessment, the process of intubation, and weaning to extubation.

TABLE 17–1 Indications for endotracheal intubation in critical care.

Hypoxemic respiratory failure	ARDS Cardiogenic pulmonary edema Pneumonia Status asthmaticus
Hypercapnic respiratory failure	COPD exacerbation
Circulatory failure	Shock/cardiac arrest Anticipated hemodynamic instability
Neurologic emergency	Treatment of increased ICP
Airway protection	Airway edema Airway obstruction (secretions/blood) Altered mental status Surgical procedures

FUNCTIONAL ANATOMY OF THE AIRWAY

The upper airway (Figure 17–1) includes all of the structures externally from the nares and mouth to the vocal cords. The nasal passage way is highly

vascular; disruption of Kiesselbach’s plexus, located in the anterior aspect of the nasal septum, is the most common cause of epistaxis. The floor of the nasal passage way slopes very gently downward. As such, nasal airways, nasogastric tubes, and endotracheal tubes (ETTs) should be directed perpendicularly or with a slightly caudad tilt in the supine patient. The nasal passages open into the nasopharynx. Laceration of the mucosa and creation of a false passage during nasotracheal intubation most commonly occurs in the region of the eustachian tubes.

The larynx is continuous with the trachea inferiorly. The thyroid cartilage, cricoid cartilage, and the hyoid bone are the main components of the laryngeal skeleton. The epiglottis and arytenoids contribute to this structure. The piriform recesses, which reside on each side of the larynx, function to divert the food bolus laterally and away from the glottic opening. The thyroid cartilage supports most of the soft tissue structures in the larynx. The cricoid cartilage is the only complete ring in the larynx and serves to support the posterior laryngeal structures. During an emergent intubation in which the patient cannot be ventilated or intubated, the cricothyroid membrane, which is located between the thyroid

FIGURE 17–1 Normal anatomy of the upper airway.

and cricoid cartilages, may be surgically accessed to obtain an airway. The epiglottis projects posteriorly from the tongue and aids in airway protection during deglutition. Arytenoid cartilages articulate with the posterior parts of the cricoid cartilage. The muscles of voice control are attached to the two arytenoid cartilages, and the vocal cords project anteriorly from the arytenoid cartilages to the thyroid cartilage. Movement of the cricoarytenoid joints from the action of the laryngeal muscles causes a change in size of the opening between the vocal cords. The larynx is heavily innervated by the vagus nerve.¹

The trachea starts at the inferior border of the cricoid cartilage and extends 12 to 15 cm distally to the carina, the first branch point marking the start of the right and left main bronchus. The anterior portion of the trachea is composed of structured cartilaginous rings, while the posterior portion is membranous. The average internal diameter is 9 to 15 mm. Typically, an ETT with an internal diameter of 7 to 7.5 and 7.5 to 8.5 mm is used for intubation of adult female and male patients, respectively. If bronchoscopy is anticipated, the minimum ETT size is 7.5 mm to allow passage of the bronchoscope. In some circumstances, such as pregnancy, a smaller ETT could be required due to swelling and edema of the airway.²

AIRWAY EVALUATION

Predictors of Difficult Ventilation

Bag valve mask (BVM) ventilation is a fundamental skill in airway management. Adequate ventilation is essential to provide oxygenation and removal of carbon dioxide. The American Society of Anesthesiologists (ASA) Task Force on Management of the Difficult Airway described difficult mask ventilation as a situation where a conventionally trained anesthesiologist experiences difficulty with ventilation due to one or more of the following problems: inadequate mask or supraglottic airway seal, excessive gas leak, or excessive resistance to the ingress or egress of gas.³ Fortunately, the incidence of difficult ventilation in the operating room is relatively low at 1.4% to 5%, with the incidence of impossible ventilation at 0.006% to 0.15%.⁴⁻⁶ Likely, the incidence of both situations is higher outside of the controlled setting of the operating room.

The predictors of difficult mask ventilation include factors that prevent proper seal of the mask and that obstruct air flow to and from the lungs. Identified risk factors for difficult ventilation are of age greater than 55, body mass index greater than 26, edentulous, history of snoring, and the presence of a beard.⁷ The risk factors associated with impossible ventilation include a history of neck radiation, male sex, history of sleep apnea, Mallampati III or IV score, and the presence of a beard.⁴

Predictors of Difficult Tracheal Intubation

Tracheal intubation is the process by which the airway is secured by placing an ETT past the vocal cords and into the trachea to facilitate ventilation and oxygenation. The difficulty of intubation and the difficulty of ventilation should be considered as two distinct issues. In some instances, they may be concordant, such as with Ludwig's angina, where swelling of the posterior aspect of the tongue can interfere with both intubation and ventilation. However, in other situations, the ability to intubate and ventilate may be mutually exclusive. A male patient with a large bushy beard may be difficult to ventilate with a BVM, but easy to intubate. Conversely, a thin patient with severe rheumatoid arthritis affecting the cervical spine may be easy to ventilate, but extremely difficult to intubate due to limited range of motion of the neck.

The ASA has defined the difficult intubation as a situation involving "three or more laryngoscopic attempts to place the ETT into the trachea" or a situation where the attempts last for more than 10 minutes using conventional laryngoscopy.⁸ In the operating room, the incidence of difficult intubation is around 5.8%. In the nonoperative emergent setting, the incidence varies from 10% to 24%.⁸⁻¹⁰ Patients who were difficult to intubate had a 51% incidence of life threatening complications defined by death, cardiac arrest, cardiovascular collapse, shock, or hypoxic injury.⁸ A difficult intubation increased the incidence of esophageal intubation, aspiration, pneumothorax, dental injury, and death in those requiring emergent intubation.¹² Identifying patients who may be a difficult intubation is essential. By anticipating a difficult intubation, advance

airway equipment can be procured and additional personnel, such as a more experienced laryngoscopist or a surgeon experienced in emergent surgical airways can be assembled for help.

The probability of a difficult airway may be predicted by a thorough upper airway exam. “LEMON” is a mnemonic tool that can be used in assessing and predicting the difficult airway. The mnemonic stands for: L = look externally, E = evaluate using the 3-3-2 rule (a minimum of 3 finger breadths for the mouth opening measured as the distance between the top and bottom incisors, 3 finger breadths for the thyromental distance, and 2 finger breadths for the distance between the hyoid and thyroid), M = Mallampati score (Figure 17–2), O = obstruction (anything that might interfere with intubation, such as a foreign body), and N = neck mobility. Numerous prediction models and scores have been devised and validated for the prediction of a difficult intubation.¹¹ Most of these scores are comprised of a mix of patient characteristics, disease characteristics, and operator characteristics, and have been validated in the operating room. One multicenter study evaluated the usefulness of the MACOCHA score, which consists of several risk factors that can be easily evaluated in the intensive care unit (ICU), to predict difficult intubations (Table 17–2). A score of 0-3 is associated with a low incidence of difficult intubation, while a score of 10-12 is associated with a very

TABLE 17–2 Derivation of the MACOCHA score.

	Variables	Score
Patient-related factors	Mallampati score of 3 or 4	5
	Obstructive sleep apnea	2
	Reduced cervical spine mobility	1
	Limited mouth opening < 3 cm	1
Pathology-related factors	Coma	1
	Severe hypoxemia	1
Operator-related factors	Nonanesthesiologist	1
Total score		12

high incidence of difficult intubation.⁸ An easy intubation is predicted by a large mouth opening, lack of top teeth, adequate thyromental distance, and adequate range of motion of the neck. A small mouth opening, protruding top teeth, short thyromental distance, and decreased range of motion of the neck conspire to prevent adequate alignment of the oral and pharyngeal axes during laryngoscopy and decreases the probability of visualization of the glottis (see “Visualizing the Larynx”). A normal airway

FIGURE 17–2 Mallampati score.
Class 1: Complete visualization of the soft palate
Class 2: Complete visualization of the uvula
Class 3: Partial visualization of the uvula
Class 4: Soft palate cannot be visualized (Reproduced with permission from Manabe Y, Iwamoto S, Miyawaki H, et al: Mallampati classification without tongue protrusion can predict difficult tracheal intubation more accurately than the traditional Mallampati classification, *Oral Science International* 2014;11(2):52-55.)

can subsequently become difficult due to processes, such as angioedema.

History of a prior difficult intubation appears to be strongly predictive of a difficult airway.¹³ The association between obesity and difficult airway has been studied. Though a link between the two would be expected, Brodsky et al showed in their study that obesity as an isolated factor does not increase chance of difficult intubation.¹⁴ Ultrasound has been proposed as a method of identifying patients with difficult airway. The recommended technique is to image and measure the soft tissue thickness over the vocal cords. These studies have had variable outcomes; at this time, ultrasound cannot be recommended as a definite tool to identify a difficult airway.^{15,16}

PREOXYGENATION

A key step in securing an airway is to maintain adequate oxygenation in the peri-intubation period. Prolonged periods of hypoxia can result in significant hemodynamic instability and hypoxic brain injury. Preoxygenation increases the safety buffer time available during the process of intubation. The terms safe period of apnea and duration of apnea without desaturation (DAWD) have been defined as the peri-intubation period where the patient is apneic and still able to maintain saturation more than 90%.¹⁷

During an elective intubation for general anesthesia in the operating room, the patient is preoxygenated prior to induction of anesthesia. Following induction, the patient is ventilated until the optimal intubation conditions are achieved. For the period of time required for the actual intubation, the patient remains apneic; however, the aforementioned maneuvers typically prevent desaturation. Emergent intubations are not as slow and controlled as elective intubations. In addition, patients undergoing emergent intubations are typically presumed to be full stomachs, where the benefit of ventilation prior to intubation must be weighed against the risk of insufflating the stomach and increasing the risk of aspiration.

Oxygen can be delivered by a simple face mask providing a FiO_2 of 60% to 70% or a nonrebreather (NRB) face mask with a reservoir bag providing a FiO_2 of greater than 90%. A BVM may be required

for preoxygenation prior to intubation; however, its use increases the risk of gastric insufflation and aspiration even if used properly.¹⁸ Irrespective of how the oxygen is delivered, the flow rate must be high enough to wash out all nitrogen from the circuit prior to delivery to the patient. This is typically accomplished by using high flow rates of 10 to 15 L/min. In patients who have failed a trial of NIPPV, preoxygenation may be more efficient using the NIPPV circuit than switching to NRB mask. NIPPV may also be considered for preoxygenation in morbidly obese patients and in those patients that cannot support a SaO_2 of greater than 95% by other means of oxygen delivery.¹⁹ Preoxygenation can be improved by having the patient in a sitting up or reverse Trendelenburg position so to increase their total respiratory system compliance and subsequently their functional residual capacity (FRC) and DAWD.²⁰ Failure of preoxygenation most commonly occurs due to low oxygen flow rates, inadequate preoxygenation time, air leak, and rebreathing.¹⁷

INTRAVENOUS ANESTHETICS

Intravenous anesthetics play an important role in airway management. They permit rapid induction of anesthesia and facilitate securing of the airway with an ETT with minimal stress to the patient. The ideal medication would provide amnesia, analgesia, and muscle relaxation. In addition, the ideal medication would have minimal effect on the patient's hemodynamics, preventing both hypotension due to sedation and analgesia and hypertension from the stimulation of laryngoscopy. Unfortunately, no one medication encompasses all of these properties. Instead, a balanced approach with a combination of medications is utilized. In elective intubations, the availability of time and the presence of an empty stomach allow for premedication; this is followed by an induction agent, which provides unconsciousness, and then a paralytic to help facilitate intubation. In emergent intubations, premedication may not be possible due to the lack of time or a contraindication to its use such as a full stomach. The hemodynamics of the patient may limit the amount of induction agent utilized; those who are particularly tenuous may not tolerate any induction agent. If paralysis is required, only fast acting paralytics will be of benefit

TABLE 17–3 Common endotracheal intubation medication indications and dosages.

Indication	Medication Class	IV dose	Onset
Premedications			
Midazolam	Benzodiazepine	1-2 mg	60-90 s
Fentanyl	Opioid	1-3 mcg/kg	< 30 s
Lidocaine	Local anesthetic	1.5 mg/kg	45-90 s
Induction agents			
Propofol	GABA receptor agonist	1-2 mg/kg	15-45 s
Etomidate	Imidazole	0.3 mg/kg	15-45 s
Ketamine	NMDA receptor antagonist	1-2 mg/kg	30 s
Paralytics			
Succinylcholine	Depolarizing	1.5 mg/kg	60-90 s
Rocuronium	Nondepolarizing	0.6-1.2 mg/kg	60-120 s

during an emergent intubation. Common medication dosages are listed in [Table 17–3](#).

Premedication

Midazolam

Midazolam is a fast-acting intravenous benzodiazepine that allows for anxiolysis and anterograde amnesia by crossing the brain blood barrier and activating the gamma-butyric acid (GABA) receptor complex. The acidic nature of the intravenous preparation keeps midazolam in solution; however, exposure to the pH of the blood causes a structural change making midazolam extremely lipophilic. Hepatic metabolism results in formation of an active metabolite (1-hydroxymidazolam), which is renally cleared and may contribute to prolonged sedation with extended infusions. The short duration of action is aided by its lipophilicity, which promotes rapid redistribution from the brain to inactive tissue sites, such as fat and skeletal muscle. Side effects include respiratory depression, especially when given in conjunction with an opioid.²¹

Fentanyl

Fentanyl is a synthetic centrally acting opioid agonist that is structurally related to meperidine. It is approximately 100 times more potent than morphine. The rapid onset of action is attributed to its high lipophilicity, which also leads to its short duration of action by redistribution. Hepatic metabolism results in an inactive metabolite. Side effects include respiratory depression, especially when given with a benzodiazepine, and chest wall rigidity at high doses.²¹

Lidocaine

Lidocaine is an amide local anesthetic that is capable of suppressing the sympathetic response to intubation by inhibiting the gag and cough reflex. Blunting the sympathetic response can limit the rise in blood pressure due to manipulation of the airway during intubation and can prevent an increase in intracranial pressure (ICP) in a patient with known or presumed head injury.²¹

Induction Agents

Propofol

Propofol is an alkylphenol compound that is insoluble in water, and therefore, must be administered as an emulsion, containing soybean oil, glycerol, and egg lecithin. The rapid onset of action is attributed to its high lipophilicity. The short duration of action is primarily due to redistribution from highly perfused compartments such as the brain to the poorly perfused compartments such as skeletal muscle. In addition to its hypnotic properties, propofol is both a respiratory and cardiac depressant. Hypotension following induction is primarily due to vasodilation; however, the baroreceptor response is also attenuated preventing an adequate increase in heart rate to compensate for the decrease in blood pressure.²² Hypotension following emergent intubation in critically ill patients is a strong predictor of mortality.²³ As a result, propofol should be used with caution if at all in hypotensive patients requiring emergent intubation. Hypotension should be immediately treated with a vasopressor, such as phenylephrine (IV dose 50-200 mcg).

Etomidate

Etomidate is a carboxylated imidazole that acts as a hypnotic by inhibiting the GABA receptors of the reticular activating system. Etomidate is poorly soluble in water and therefore is administered in a 35% propylene glycol solution. Onset of action is similar to propofol with a duration of effect of 3 to 12 minutes. Unlike propofol, etomidate has minimal effects on myocardial contractility and cardiac output resulting in less hypotension.²¹ Myoclonus caused by a disinhibitory effect on the central nervous system is characteristic. A single induction dose of etomidate causes adrenal suppression by inhibiting the activity of 11- β -hydroxylase, an enzyme required for cortisol and aldosterone synthesis.^{24,25} Subgroup analysis in the Corticus trial indicated a decreased responsiveness to cortisol and increased mortality in septic patients who received etomidate.²⁶ In summary, etomidate is an attractive induction agent in hemodynamically unstable patients; however, recent studies demonstrating adrenal suppression and increased mortality in septic patients has called its use into question.

Ketamine

Ketamine is a phencyclidine derivative that causes a dose-dependent state of “dissociative anesthesia” that produces both amnesia and analgesia. Ketamine interacts with a variety of receptors. Its amnesic property is likely due to the inhibition of the N-methyl-d-aspartate (NMDA) complex. Stimulation of the sympathetic nervous system causes an increase in heart rate, myocardial contractility, and mean arterial blood pressure, making it an ideal agent in hemodynamically compromised patients.²⁷ The mechanism of this indirect stimulatory effect is via inhibition of norepinephrine reuptake. The direct myocardial depressant effect of ketamine may be unmasked in patients with poor catecholamine stores such as the chronically or severely critically ill patient. Stimulation of the sympathetic nervous system will also result in increased cerebral oxygen consumption, cerebral blood flow, and ICP making it a poor choice in patients with suspected head injury and elevated ICP. Ketamine is infamous for its ability to cause hallucinations; however, the coadministration of a benzodiazepine can usually attenuate this effect.²⁸

Paralytics

Succinylcholine

Succinylcholine (SCh) is a depolarizing neuromuscular blocking drug (NMBD) that has a fast onset time and short duration of action, making it ideal for rapid sequence induction (RSI). Structurally, SCh is related to acetylcholine (ACh) and functions by binding to the ACh receptor on the motor end plate, resulting in continued depolarization of the receptor and subsequent skeletal muscle paralysis. The onset of paralysis is typically preceded by fasciculations, which are caused by transient generalized skeletal muscle contractions. Normal muscle function does not return until the receptor is allowed to repolarize to its resting state, which occurs after metabolism of SCh by pseudocholinesterase. Pseudocholinesterase metabolizes SCh at such a high rate that only a small portion of the injected dose reaches the motor end plate. Altered pseudocholinesterase function can result in paralysis lasting 6 to 8 hours after a single dose. A relative decrease in pseudocholinesterase levels in patients with liver disease, kidney disease, anemia, pregnancy, and cocaine and amphetamine abuse has a minimal clinical effect and no alteration in the dose of SCh is required.²⁹

Certain adverse effects may prevent SCh from being utilized as a RSI paralytic. On average, the serum potassium level increases 0.5 mEq/L following administration of SCh. If a paralytic is required in a patient with symptomatic hyperkalemia, an alternative medication should be considered; however, renal failure in a patient with normal potassium levels is not a contraindication to the administration of SCh.³⁰ Severe hyperkalemia causing cardiac arrest has been documented in patients with disorders of the nervous system (eg, spinal cord transection, amyotrophic lateral sclerosis, Guillain-Barre, etc) or extensive burn injury. Approximately 5 to 15 days after an acute injury, the body produces extrajunctional ACh receptors (ie, outside of the motor end plate) that may cause excessive potassium release following administration of SCh. This phenomenon puts patients at increased risk of hyperkalemic cardiac arrest. Nonetheless, it is generally considered safe to administer SCh within 24 hours of the acute injury nerve injury or stroke.³¹ Hyperkalemia may also occur in patients with disorders

of the musculoskeletal system, such as Duchenne muscular dystrophy, and SCh should be avoided in such patients. The increase in potassium level after SCh administration has been associated with length of stay in the ICU, which acts a surrogate marker for immobility. The risk of acute hyperkalemia (≥ 6.5 mEq/L) is highly significant after 16 days in the ICU.³²

The administration of SCh increases intraocular pressure (IOP) by 5 to 10 mm Hg for 2 to 6 minutes.³³ In patients with open eye injuries, the concern that increased IOP will cause extrusion of intraocular contents has limited the use of SCh in these patients. Nonetheless, there has never been a reported case of this occurring in the literature. The effect of SCh on ICP is controversial. Studies demonstrating a modest increase in ICP after SCh administration are inconsistent.³⁴ SCh may act as a trigger for malignant hyperthermia, a life-threatening complication resulting in high fever, muscle rigidity, rhabdomyolysis, and renal failure, which requires immediate treatment with dantrolene. Fortunately, the incidence of malignant hyperthermia after administration of SCh is rare. While SCh may cause a number of potential adverse side effects, no medication has been able to match its fast onset time and short duration to replace it as the paralytic of choice during an emergent intubation.

Rocuronium

Rocuronium is a nondepolarizing NMBD that causes paralysis by antagonism of the ACh receptor. The onset of action is slightly slower than that of SCh at a rapid sequence intubating dose of 1.2 mg/kg (normal intubating dose 0.6 mg/kg), but faster than the other nondepolarizing NMBDs. The major concern with rocuronium is its prolonged duration of action of approximately 1 hour. If a patient needs to be woken up due to difficulty in intubating or ventilating, they will not be able to regain spontaneous respiration for a prolonged period of time. Sugammadex is a specific reversal agent for rocuronium, preventing its interaction with the ACh receptor, and reverses paralysis within 3 minutes of administration.³⁵ Sugammadex is currently not available in the United States due to Food and Drug Administration concerns regarding hypersensitivity and allergic reactions.

BAG MASK VENTILATION

The ability to oxygenate and ventilate a patient is an essential skill for anyone involved in airway management. While much emphasis is often placed on the ability to intubate, the morbidity associated with emergent intubations is in fact more closely correlated to the inability to ventilate and provide gas exchange. When an unanticipated difficult airway is encountered, the ability to ventilate the patient allows the practitioner to breathe for the patient, allowing time to obtain help in the form of additional equipment or personnel. Many practitioners insist that the ability to ventilate a patient be demonstrated prior to the administration of a paralytic. Paradoxically, ventilation can be made easier by paralysis due to loss of muscular tone. In addition, the administration of a paralytic can be crucial in increasing the intubatability of a patient assessed to be a moderately difficult airway. Ventilation with a BVM is relatively contraindicated during rapid sequence intubation (RSI) as it can lead to insufflation of the stomach and increase the risk of aspiration.

Facemasks for BVM are available in multiple sizes. Clear masks have the benefit of allowing visualization of vapor condensation, skin color, and signs of regurgitation. The last three digits of the practitioner's left hand are utilized to open the patient's airway with either a chin lift or jaw thrust. Compression of the soft tissue below the mandible should be avoided to prevent obstruction of the airway. The thumb and index finger are utilized to hold the facemask in place. The bag mask ventilation is a self-inflating resuscitation bag with reservoir connected to a high-flow oxygen source.³⁶

Maintaining an open airway is one of the first steps required to insure adequate ventilation. Typically, a head tilt chin lift position is used. However, in patients with suspected spinal injuries, a jaw thrust maneuver is performed. Adjuncts, such as oral and nasal airways can be used to improve ventilation by moving an obstructing tongue from the posterior pharyngeal wall. In lightly anesthetized patients, an oral airway may trigger the gag reflex with a nasal airway being better tolerated. Nasal airways are relatively contraindicated in patient on blood thinners and antiplatelet therapy due to the risk of epistaxis and in any patient with a suspected basilar skull

fracture. In a patient who is difficult to ventilate despite these maneuvers and adjuncts, a two person technique may be required. One person opens the airway using two hands and the other ventilates the patient.³⁷⁻³⁹ The adequacy of BVM ventilation may be assessed by looking for chest rise and condensation on the mask due to the return of humidified exhaled air.

SUPRAGLOTTIC DEVICES

Laryngeal Mask Airways

The first supraglottic device was the laryngeal mask airway (LMA) classic invented by Dr Archie Brain in 1981. The first-generation LMA device was a reusable device, but a disposable version was soon developed. The LMA consists of a ventilation tube and an elliptical mask with a cuff, pilot tube, and balloon. Aperture bars in the mask prevent the epiglottis from obstructing ventilation. When inserted, the LMA moves along the hard then soft palate to the hypopharynx and then resides in the proximal esophagus, ultimately acting as a “mask” for the glottic opening with the distal tip located posterior to the cricoid cartilage and the proximal portion against the base of the tongue. Advantages of LMA use during general anesthesia include less irritation to the vocal cords and decreased hemodynamic changes upon awakening. Since its introduction, the use of LMAs has been extended from purely elective use to rescue situations where a patient cannot be ventilated. Other variations in the LMA have evolved and include the flexible LMA, ProSealLMA, LMA supreme, and LMA Excel. The Fastrach LMA was designed to aid with intubation as well as ventilation. Other supraglottic devices such as the Ambu laryngeal mask, Air Q intubating laryngeal airway, Cobra perilaryngeal airway, and others are based on the same concept as the LMA.

Combitube

The Combitube was developed for patients that could not be intubated by traditional laryngoscopy. The device is designed to be inserted blindly. Ventilation can be supported regardless of whether the distal portion of the tube is placed in the esophagus or trachea. The tube is a disposable, double lumen, and

double cuffed device with separate pilot balloons for the proximal and distal cuffs. Approximately 95% of the time the distal tip of the tube enters the esophagus allowing the lungs to be ventilated via the proximal lumen. Less than 5% of the time, the tip of the tube enters the trachea and ventilation occurs via the distal lumen. Disadvantages of the Combitube include the inability to suction the trachea when the distal tip of the tube is in the esophagus. Contraindications for the use of the Combitube include patients with esophageal disease, suspected caustic substance ingestion, and history of esophageal varices.^{41,42}

TRACHEAL INTUBATION

Tracheal intubation consists of three steps: visualization of the larynx, placement of the ETT proximal to the larynx, and then advancement of the ETT distal to the glottis.

Visualizing the Larynx

Laryngoscopic visualization of the vocal cords is made easier when the patient is placed in the sniffing position. The sniffing position, which is defined as flexion of the neck on the body and extension of the head on the neck, may be achieved by elevating the head in the extended position.⁴³ In the sniffing position, the oral and pharyngeal are placed into greater alignment facilitating direct visualization of the glottis (Figure 17-3). Modifications to patient positioning such as ramping up of the morbidly obese patient can lead to improved visualization as well (Figure 17-4).

Direct laryngoscopy involves using a laryngoscope, which contains a handle, blade and light source. Laryngoscope blades come in a variety of shapes and sizes. The most commonly used blades include the Macintosh and Miller blades. The curved Macintosh blade requires insertion in the right corner of the mouth, sweeping the tongue to the left with concurrent insertion, and placement of the tip into the vallecula, which indirectly elevates the epiglottis. The Miller, or straight blade, is inserted under and directly lifts the epiglottis. The choice of the blade is typically operator dependent; however, a straight blade that directly lifts the epiglottis may work better in certain situations such as with a patient with a large floppy epiglottis.⁴⁴

FIGURE 17-3 Sniffing position for endotracheal intubation—head extended and neck flexed.

Confirmation of Endotracheal Placement of ETT

The best confirmation of tracheal placement of an ETT is by directly visualizing the tube passing through the vocal cords. Other confirmatory measures may be utilized including bilateral breath sounds, rise and fall of the chest wall, and condensation on the ETT. Capnography detects the presence of carbon dioxide in the exhaled air and is another positive indicator of tracheal intubation. False negatives may occur in the presence of decreased pulmonary blood flow, such as with a cardiac arrest or with airflow limiting processes, such as bronchospasm.

Rapid Sequence Intubation

RSI is typically utilized in situations where the risk of aspiration is deemed to be high due to known or suspected full stomach, physiological conditions, such as late-term pregnancy, and pathological conditions, such as bowel obstruction or severe ascites. The goal of RSI is to decrease the risk of aspiration by minimizing the time between loss of airway reflexes, which occurs upon induction of anesthesia, and protection of the airway by ETT placement. RSI is accomplished by preoxygenation, application of cricoid pressure, administration of an induction agent and paralytic, and then intubation when the paralytic has come into full effect.

FIGURE 17-4 Improved Cormack–Lehane view with head elevation.

The goal of applying downward pressure at the cricoid cartilage is to prevent regurgitation of stomach contents by collapsing the esophagus between the trachea and spine. The utility of this maneuver has recently been called into question and may in the future be removed from the algorithm.⁴⁰ If cricoid pressure obscures the view of the vocal cords, it should be stopped immediately. In order to lessen the time between induction and intubation, only fast acting induction agent and paralytic should be chosen, and the two agents should be administered in rapid succession. As discussed in “Intravenous Anesthetics,” SCH provides paralysis with a fast onset and short duration. When a contraindication to SCH exists, “double-dose” rocuronium (twice the usual intubating dose of 0.6 mg/kg, ie, 1.2 mg/kg)

provides an onset of paralysis nearly as fast as SCH, but with a prolonged duration of action. Ventilation with a BVM is typically avoided in order to prevent insufflation of the stomach with air, which increases the risk of aspiration. However, if the risk of injury from hypoxemia is judged to be greater than the risk of aspiration, manual ventilation should be utilized. In addition, injury from hypercarbia may also necessitate ventilation if the intubation is not immediately successful. [Table 17-4](#) outlines various conditions where ventilation during RSI may need to be utilized. RSI is contraindicated in the setting of a known difficult airway. In this circumstance, an awake intubation will maintain protective airway reflexes while the airway is being secured.

TABLE 17–4 Indications for ventilation during RSI.

Severe hypoxemia
Conditions where worsening hypercapnia would be deleterious:
Cerebral edema or high ICP
Severe pulmonary hypertension
Right heart failure
Severe metabolic acidosis
Hyperkalemia

INDIRECT LARYNGOSCOPY

Videolaryngoscopy

Recently, a number of devices that utilize a high-resolution camera and a small monitor screen have been developed to improve the view and the success rate of intubation over that of direct laryngoscopy. All of these devices allow a view of the glottis without requiring alignment of the oral and pharyngeal axes (Figure 17–3). The learning curve of these newer devices appears to be less than that of direct laryngoscopy, especially for novice laryngoscopists.⁴⁵

Fiberoptic Intubation

The gold standard for management of an anticipated difficult airway is fiberoptic intubation. Fiberoptic intubation via the nasopharynx as compared to the oropharynx is technically easier because of the gentler curve toward the glottis, but the high vascularity of the nasal passage increases the incidence of bleeding which can interfere with fiberoptic visualization of the glottis. Subsequently, an inherent weakness of the fiberoptic bronchoscope is that the camera view can easily be obscured by any contamination of the larynx. In addition, fiberoptic bronchoscopy is a modality that is not easily utilized during a truly emergent intubation.

In an awake, nonemergent fiberoptic intubation the patient is instructed about the procedure. The upper airway is topicalized with local anesthetic such as 4% lidocaine. Mild sedation typically aids in the patient tolerating the intubation; however, care must be taken not to over-sedate the patient, causing respiratory depression. Pretreatment with glycopyrrolate, a potent antisialagogue, decreases secretions. If time allows, a topical vasoconstrictor to the nares

can help prevent bleeding. If the oral approach is attempted, a bite block will prevent damage to the fiberoptic scope. Once the tip of the scope is advanced past the glottis the ETT is advanced. Frequently, full advancement of the tip of the ETT into the trachea is hindered by the arytenoids. Gentle pressure and a clockwise rotation usually allow passage into the trachea. The correct position of the tube can then be confirmed by bronchoscopy.⁴⁶

Other Techniques

In patients that are spontaneously breathing and cannot be intubated orally or have failed traditional oral intubation, a blind nasal intubation can be utilized to secure the airway. This procedure became popular during pre-hospital intubations when the use of paralytics was restricted. Typically the ETT is lubricated to aid in insertion. If time allows, the nasal passage way can be pretreated with a vasoconstricting agent to minimize bleeding. As the ETT is advanced from the nasopharynx to the oropharynx, the transmission of breath sounds via the tube are used to guide advancement through the glottis. Complications of this procedure include epistaxis, sinusitis, turbinate injury, perforation of the pharynx, and failed intubation and loss of airway. Contraindications include patients who are not spontaneously breathing and suspected basilar skull^{47,48} or neck injuries.

LMAs have officially been identified as a rescue device during difficult intubation as well as ventilation. The Fastrach LMA was specifically designed to allow ventilation as well as to facilitate intubation. It differs from the classic LMA by having an anatomically curved rigid airway tube, integrated guiding handle, epiglottic elevating bar, and a guiding ramp. A Fastrach LMA with an internal diameter of 13 mm can accommodate up to an 8.0 sized lubricated ETT. The insertion technique of the Fastrach LMA is similar to other LMAs; however, after insertion, it is recommended to first rotate the Fastrach LMA in the sagittal plane to align with the glottis opening and then to move the metal handle vertically to prevent pressure on the arytenoids. Once in place with the cuff inflated, this LMA can be used to ventilate the patient. The ETT is inserted blindly through the LMA, although this method can be modified by use of the fiberoptic bronchoscope if

blind insertion is not successful. After insertion, the LMA must be removed very carefully with an obturator holding the tube in place. In certain circumstances, the LMA may be deflated and left in place if risk of tube displacement is high. Complications of the intubating LMA include esophageal intubation, injury to the larynx and teeth, and aspiration of gastric contents.^{49,50}

SURGICAL AIRWAY

If a patient cannot be intubated, one of two options remains. The first is to continue ventilating the patient and to allow them to awaken from sedation. The second option is to proceed to a surgical airway, which may need to be performed emergently if the patient cannot be ventilated or intubated. Cricothyroidotomy involves placement of an airway device by piercing the cricothyroid membrane. The prevalence of out-of-hospital cricothyroidotomy placement by emergency services varies based on location—from 4/100,000 overall up to 10% in a single center study.^{51,52} The cricothyroid membrane is located above the cricoid cartilage and 1 to 1.5 fingerbreadths below the thyroid cartilage in the midline of the neck. The airway can be entered by a surgical technique that involves a vertical skin incision, blunt dissection down to the trachea, and a horizontal incision in the trachea. Otherwise, the airway is entered by a percutaneous puncture technique. Confirmation of successful placement of the airway into the trachea involves capnography, chest auscultation and a confirmatory chest x-ray. Generally, the cricothyroidotomy is converted to a regular tracheostomy within 24 hours, provided the patient has stabilized.⁵³

ENDOTRACHEAL TUBE EXCHANGE

Despite proper care and suctioning, an ETT may need to be exchanged for a host of reasons such as development of a pilot balloon leak or tube obstruction. One method to exchange the tube is to induce anesthesia with or without a paralytic, remove the ETT, and reintubate the patient. Even if the patient was originally an easy intubation, it is not uncommon for airway swelling and edema to make a subsequent

reintubation more difficult. If the patient was originally a difficult airway or the patient's condition has changed and a difficult airway is now anticipated, a safer method of changing the ETT may involve using an airway exchange catheter (AEC). These catheters are thin, elongated, hollow tubes. Various sizes and diameters are available ranging from the Cook AEC (8-11 Fr) to the Aintree intubating catheter (14Fr). These tubes come with a ventilation port that can be used to oxygenate the patient if reintubation becomes prolonged.⁵⁴ The AEC is inserted through the ETT until resistance is encountered, usually between 30 and 40 cm. Some studies now suggest that the AEC should not be inserted more than 23 cm to prevent injury to the lung.⁵⁵ The indwelling ETT is removed and a new ETT is advanced over the catheter. Advancement of the tip of the ETT can be impeded by the posterior arytenoids. Gentle rotation in a clock-wise fashion will typically allow passage. The first pass success rate of reintubation over an AEC is 80% to 90%. If unable to pass the tube into the trachea, direct or indirect laryngoscopy may be required for reintubation. If that fails, a surgical airway may be emergently required. Complications associated with AEC use are direct injury to the airway by the catheter, which can on rare occasion lead to a pneumothorax.^{56,57}

EXTUBATION

Critically ill patients are intubated for a host of different reasons that range from respiratory failure to prophylactically securing the airway. Objective clinical criteria and weaning predictors help predict if a patient is ready to be extubated. The required and optional criteria are listed in [Table 17-5](#).⁵⁸ The rapid shallow breathing index (RSBI), which compares the respiratory frequency to the tidal volume (f/V_T), is the most commonly used and best studied weaning parameter. A RSBI of more than 105 breaths/min/L suggests that that patient is not ready to be liberated from the ventilator. As a patient is being weaned from support on the ventilator, they can be placed on a spontaneous breathing trial (SBT) either with a progressive pressure support wean with or without PEEP or with a T-piece trial. The rationale for performing a SBT with decreasing/minimal pressure support rather than no support with a T-piece trial is that the

TABLE 17–5 Required and optional criteria for tracheal extubation.

Required criteria
1. Cause of respiratory failure has improved
2. Adequate oxygenation $\text{PaO}_2/\text{FiO}_2 \geq 150$ $\text{SpO}_2 > 90\%$ on minimal vent settings
3. Arterial $\text{pH} > 7.35$
4. Hemodynamic stability
5. Adequate ventilation with a spontaneous respiratory rate and adequate tidal volume
6. Airway protective reflexes: cough, gag, swallow
7. Awake and alert or easily arousable
Optional criteria
1. Hemoglobin $\geq 7\text{--}10$ mg/dL
2. Afebrile with core temp $\leq 38^\circ\text{C}$

lumen of the ETT tends to become occluded over time, and this occlusion can cause resistance to air flow movement that is equivalent to a tube that is 1 to 4 times smaller.⁵⁹ Additional support for using low-level pressure support comes from a study that took patients who were failing a T-piece trial; after being placed immediately on pressure support ventilation at 7 cm of H_2O for 30 minutes, 21 of 31 patients were successfully weaned.⁶⁰ Common causes of weaning failures are volume overload, cardiac dysfunction, neuromuscular weakness, delirium, anxiety, metabolic disturbances, and adrenal insufficiency, in addition to unresolved lung pathology.

Following a successful weaning trial and the achievement of minimal ventilator settings, the patient’s ability to protect their airway and the patency of the airway must be assessed. The ability to protect the airway is dependent on the strength of the patient’s cough and inversely correlated with the required frequency of suctioning.⁶¹ Airway patency is commonly demonstrated with a positive cuff leak prior to extubation. A cuff leak refers to air-flow around the ETT after the cuff balloon has been deflated. The absence of a leak suggests that the space between the ETT and larynx is reduced, which places the patient at risk for postextubation stridor. A cuff leak can be quantitatively determined by placing the patient on full mechanical support and measuring the difference between the inspired tidal volume and the expired tidal volume. A difference less than 110 mL or 12% to 24% of delivered tidal volume suggests that airway patency is diminished.⁶²

Once the decision to extubate the patient has been made, the patient should be seated in an upright position. The oral cavity and ETT should be suctioned. The patient is instructed to inhale deeply and during exhalation the cuff balloon is deflated and the tube is removed. Typically, an orogastric tube is removed simultaneously with the ETT. The oral cavity is again suctioned after extubation and the patient is placed on supplemental oxygen. If the concern for postextubation failure/complication is high and the airway was not easily secured, an AEC can be left in place after extubation. Early aggressive management with bronchodilators, suctioning, diuresis, and/or NIPPV can prevent reintubation. The caveat is that NIPPV applied after the onset of postextubation complications appears to be ineffective and may be harmful; therefore, patients who are anticipated to need NIPPV after extubation should be extubated directly to NIPPV.⁶³

SPECIAL SITUATIONS

Severe Sepsis and Septic Shock

Indications for intubating patients with severe sepsis and septic shock are to reduce the work of breathing, treat hypoxic respiratory failure, and for airway protection in patients with septic encephalopathy. Typically, these patients must be assumed to be a full stomach with a RSI as the preferred method of intubation. Etomidate is typically used as the induction in hypotensive patients because it causes less vasodilation than propofol. However, a growing amount of evidence argues against its use in this patient population.^{64–66}

Head Injury

Head-injured patients are specifically at a higher risk of worsening neurologic injury with increasing ICP. The act of laryngoscopy, intubation, and tracheal suctioning has been shown to induce a sympathetic response,⁶⁷ which causes an increase in the systemic blood pressure and subsequently can lead to increased ICP. A balance must be obtained between RSI, which tends to elicit more hemodynamic lability, but may protect against aspiration, versus a slower and gentler induction and intubation, which may mitigate increases in blood pressure and ICP,

but may increase the risk of aspiration. A complicating aspect is the fact that hypotension is also detrimental to these patients. Increasing the amount of narcotic administered during induction can block the sympathetic response with minimal effect on systemic blood pressure; however, the sedative effects will last longer than with propofol or etomidate and may interfere with the postintubation neurological exam. Esmolol is an ultrashort acting β -blocker that can block sympathetic stimulation; however, care must be taken to not cause hypotension.⁶⁷

Lidocaine is a local anesthetic that can also block the sympathetic response to intubation for a few minutes with minimal effect on blood pressure and effect on the postintubation neurological exam.^{68,69} Muscle relaxation with SCh might cause a temporary rise in ICP.⁶⁷ Pretreatment with a low dose of nondepolarizing neuromuscular blocker (NDMB) can attenuate this effect; however, this technique should not be used in an anticipated difficult airway because even that small dose of a NDMB can interfere with waking a patient up after a failed intubation attempt and may drive the algorithm toward a surgical airway. The patient with suspected head injury should be positioned with the head up at least 30° to facilitate venous drainage and mitigation of the ICP.⁷⁰ Hyperventilation should only be utilized for the emergent treatment of impending cerebral herniation.

Cervical Spine Injury

All trauma patients are assumed to have a cervical spine injury unless proven otherwise. Studies have estimated that all airway devices cause some degree of extension of the cervical spine. In a cadaver study, the McCoy laryngoscope caused maximal extension at the C₀-C₁ level and the Macintosh caused maximal extension at the C₂-C₃ level.⁷¹ While the least amount of cervical manipulation occurs with fiberoptic intubation, direct laryngoscopy may still be required in the patient with an unstable C-spine if the airway must be secured emergently.⁷² In order to secure the airway without causing movement at the C-spine, manual inline stabilization is mandatory. The C-collar is removed and an assistant stands at the head of the stretcher and gently, but firmly maintains the head in a neutral position during laryngoscopy.⁷³

Cardiac Arrest

The latest ACLS guidelines from the American Medical Association emphasize good chest compressions and ventilation with end-tidal carbon dioxide (EtCO₂) monitoring over placement of an advanced airway.⁷⁴ If BVM ventilation is ineffective, then a supraglottic device, such as a LMA can be placed fairly quickly. If endotracheal intubation is to be attempted, it is usually done without any sedation or paralysis. Tube placement is confirmed by visualizing the ETT going through the vocal cords as well as with auscultation and positive capnography. The positivity of capnography may be diminished due to decreased pulmonary blood flow.

SUMMARY

Airway management is the process by which differing degrees of respiratory failure are treated. Mild respiratory failure may only require supplemental oxygen via a nasal cannula, while more severe forms of respiratory failure may require endotracheal intubation. The intensivist must be facile with all aspects of securing the airway including assessment of the anticipated ease or difficulty of ventilation and intubation, the role of RSI, the anesthetic agents to be utilized, and the advanced equipment available for placing an ETT in the trachea. Of even greater importance is the ability to recognize the unanticipated difficult airway and to call for help immediately when difficulty with intubation or especially ventilation is encountered. In addition to securing the airway, the intensivist must be able to evaluate the safety and appropriateness of removing an ETT. These basic principles of airway management are frequently utilized in the intensive care and are foundational to the care of those critically ill with respiratory processes or in need of airway protection.

Ventilator Technology and Management

Adebayo Esan, MBBS, FCCP, FACP; Felix Khusid RRT- ACCS, NPS, RPFT, FAARC, FCCM, FCCP and Suhail Raoof, MD, FCCP, MACP, CCM

KEY POINTS

- 1 The goals of mechanical ventilation are to provide safe gas exchange, decrease the work of breathing, improve patient–ventilator interactions, minimize iatrogenic injury, and promote liberation from mechanical ventilation in a timely manner.
- 2 Mechanical ventilation is indicated in individuals who are unable to sustain normal gas exchange as a result of established or impending respiratory failure from hypoxemia, hypercapnia, or both; airway problems, and to provide support to individuals undergoing general anesthesia.
- 3 A ventilator mode can be classified by specifying the control variable, breath sequence, and targeting scheme.
- 4 Conventional modes of ventilatory support include continuous mandatory ventilation, assist-control ventilation, intermittent mandatory ventilation and synchronized intermittent mandatory ventilation, and pressure support ventilation.
- 5 Alternative modes of ventilatory support include dual control modes, such as volume-assured pressure support or pressure augmentation, volume support ventilation or variable pressure support ventilation, pressure-regulated volume control and auto mode ventilation.
- 6 Nonconventional modes of ventilatory support include airway pressure release ventilation, proportional assist ventilation, adaptive support ventilation, neurally adjusted ventilatory assist, and high-frequency ventilation including high-frequency oscillatory ventilation and high-frequency percussive ventilation.
- 7 Monitoring during mechanical ventilation includes measurement of peak and plateau pressures, intrinsic positive end-expiratory pressure, and work of breathing.
- 8 Prerequisites prior to conducting a spontaneous breathing trial include partial or complete recovery of conditions that resulted in respiratory failure; adequate oxygenation with low PEEP, that is, $\text{PaO}_2/\text{FIO}_2$ more than 200, $\text{PEEP} \leq 8 \text{ cm H}_2\text{O}$, and $\text{FIO}_2 \leq 0.5$; absence of severe acidosis ($\text{pH} \geq 7.25$); hemodynamic stability with minimal or no vasopressor support; and presence of spontaneous inspiratory effort.
- 9 Noninvasive positive pressure ventilation avoids complications of invasive ventilation (eg, trauma, cardiac arrhythmias, hypotension, volutrauma, and ventilator-associated pneumonia).
- 10 Indications for noninvasive positive pressure ventilation include acute hypercapnic respiratory failure in the setting of chronic obstructive pulmonary disease (COPD) and cardiogenic pulmonary edema and immunosuppressed patients with pulmonary infiltrates, fever, and acute respiratory failure.

INTRODUCTION

Mechanical ventilation may prove to be life-saving in patients with acute respiratory failure. The use of mechanical ventilation has evolved over the years from the application of positive pressure with bellows to negative-pressure deployment with devices like the tank respirator to the modern day complex microprocessor-controlled positive-pressure devices. In recent years, new modes of mechanical ventilation have been devised for the purpose of enhancing patient comfort, minimizing patient-ventilator dyssynchrony, reducing lung injury, and automatically escalating or deescalating ventilatory support as needed. Regardless of these advancements, the goals of mechanical ventilation remain the same: providing safe gas exchange; decreasing the work of breathing (WOB); improving patient-ventilator interactions; minimizing iatrogenic injury; improving patient-ventilator interactions; and promoting liberation from mechanical ventilation in a timely manner.¹⁻³ Nonetheless, it

must be pointed out that there is limited data to show that newer modes of mechanical ventilation reduce morbidity and mortality over conventional modes of mechanical ventilation.⁴

INDICATIONS OF MECHANICAL VENTILATION

Mechanical ventilation is indicated in individuals who are unable to sustain normal gas exchange as a result of established or impending respiratory failure from hypoxemia, hypercapnia, or both; airway problems, and for providing support to individuals undergoing general anesthesia. The decision to institute mechanical ventilation must take into account both the clinical circumstances (eg, clinical signs of respiratory distress, cardiovascular compromise, impaired mentation, reversibility of underlying disease, or presence of multiorgan dysfunction) as well as the patient’s acceptance of the treatment. The indications for mechanical ventilation are shown in [Table 18–1](#).^{5,6}

TABLE 18–1 Indications for mechanical ventilation.

Type of Respiratory Failure	Area of Involvement	Common Examples
Ventilatory failure	Central nervous system (respiratory center)	Drug overdose, narcotics or sedatives, brain injury, brain tumors, hemorrhage, infection, edema, infarction, trauma, hypothyroidism
	Spinal cord	Cervical or thoracic spinal cord injury, poliomyelitis, amyotrophic lateral sclerosis
	Peripheral nervous system	Phrenic nerve paralysis, polyneuritis, Guillain-Barre syndrome
	Neuromuscular junction	Myasthenia gravis, Lambert-Eaton disease, botulism, tick paralysis, neuromuscular blocking drugs
	Respiratory muscles	Diaphragmatic weakness, endocrine disorders, electrolytes impairment, corticosteroid usage, critical care myopathy
	Bony rib cage	Flail chest
	Airway	Laryngeal edema, airways obstruction, acute bronchospasm, profuse airway secretions
Oxygenation failure	Diffusion abnormality	Pulmonary edema, interstitial lung disease
	Shunt	Atelectasis, pneumonia, acute respiratory distress syndrome
	Cellular extraction impairment	Sepsis, carbon monoxide poisoning
	Perioperative care	Routine anesthesia, major or prolonged surgery

BASIC PRINCIPLES OF VENTILATORY SUPPORT

Ventilators are either powered electrically or pneumatically. Ventilator classification schemes serve to elucidate the mechanism by which a ventilator operates.^{7,8} Technological advancements with complex (microprocessor-controlled), dual modes with built-in intra- or interbreath feedback mechanisms have made the classification schemas more difficult. This is further compounded by the absence of a universally established classification system for ventilators.^{1,9} To add to the increasing complexity, various ventilator manufacturers have given different proprietary names for the same mode of ventilation.^{1,10,11} An example of this is adaptive pressure control (PC), which depending on the ventilator brand, is also called pressure-regulated volume control, adaptive pressure ventilation, auto-flow, volume control plus, volume-targeted PC, and pressure-controlled volume guaranteed.¹⁰ Table 18–2 outlines the essential components of a ventilator delivered breath, which gives a better understanding of how these modes work.

Equation of Motion

The equation of motion is a mathematical expression of the interaction between a patient and a ventilator, and elucidates the events within a breath.⁹ It is expressed as

$$P = V_T / C_{RS} + \dot{V} \times R$$

where P is the sum of the pressures generated by the patient and the ventilator, V_T is the tidal volume that

the patient receives (ventilator driven) or generates (intrinsic inspiratory effort), C_{RS} is the compliance of the respiratory system, \dot{V} is the flow, and R is the resistance of the respiratory system (airway tubing, endotracheal tube, and airways). Thus, V_T / C_{RS} is the elastic load and $\dot{V} \times R$ the resistive load that has to be overcome to deliver volume and flow to the patient.

Control Variables

A ventilator regulates inspiration of a mechanical breath by manipulating control variables such as pressure, volume, flow, or time as feedback signals.^{7-9,11} The control variable is based on the equation of motion expressed earlier. During inspiration, a ventilator controls one variable at a time; that is, pressure, volume, or flow. The control variable remains constant as the ventilatory load imposed by the patient's respiratory system (ie, lung compliance and airway resistance) changes.^{7-9,11} In some ventilators, neither pressure, nor volume nor flow can be kept constant with changes in the ventilatory load resulting from the patient's lung mechanics. In such ventilators, only inspiratory and expiratory times are the variables being controlled, such as is seen in high-frequency ventilation.^{8,9,11}

Phase Variables

Further description of a mechanical breath can be made by identifying what triggers (initiates), limits (sustains) and cycles (ends) a breath. These aforementioned events that initiate different phases of the ventilatory cycle (Figure 18–1) are referred to as phase variables.^{8,11} The trigger variable initiates inspiration

TABLE 18–2 Terminology used to define components of a ventilator-delivered breath.

Variable	Definitions	Parameter Used
Control	The parameter that the ventilator controls	Pressure, volume, flow, or time
Phase	Trigger—initiates inspiration	Pressure, flow, or time
	Limit—maximum level that can be reached and sustained during inspiration	Pressure, volume, or flow
	Cycle—terminates inspiration	Pressure, volume, flow, or time
	Baseline—sustains functional residual capacity	Pressure
Conditional	Determines whether change in breath pattern is needed	Pressure, volume, flow, minute ventilation, or time

FIGURE 18–1 Different components of a ventilatory breath cycle.

and could either be machine-triggered (usually timed) or patient-triggered (usually pressure or flow).^{8,11} Flow triggering has become standard in most modern ventilators and has been shown to reduce the inspiratory WOB in comparison to pressure triggering as well as enhance the patient-ventilator synchrony.^{12,13} The limit variable is the maximum preset value of pressure, volume, or flow that can be reached and sustained before inspiration ends. The preset limit value being reached does not end the inspiratory phase.^{7,8,11} The cycle variable is the preset value of pressure, volume, flow, or time that ends inspiration. In pressure, volume, or flow cycling, a ventilator delivers inspiratory flow until a preset pressure, volume, or flow is attained, after which inspiration ends and exhalation begins. With time cycling, inspiration ends once a preset inspiratory period has elapsed.^{7,8,11} Exhalation begins once inspiration ends. The baseline variable is the parameter that is controlled during exhalation. Even though pressure, volume, or flow can function as baseline variables, modern ventilators utilize pressure because it is the most practical to implement. This is done by employing the positive end-expiratory pressure (PEEP) setting such that if baseline pressure is to be equal to or exceed atmospheric pressure, PEEP is set at 0 or a positive value, respectively.^{7,8,11}

CONDITIONAL VARIABLES

A ventilator creates specific patterns of control from each breath and decides at preset intervals if that

pattern of breathing should be altered. An example of this is when a ventilator switches from a patient-triggered (spontaneous) breath to a machined-triggered (mandatory) breath in synchronized intermittent mandatory ventilation (SIMV), delivers sighs at regular intervals, or switches to mandatory minute ventilation mode.^{8,11}

BREATH SEQUENCE

The breath sequence describes the manner in which spontaneous and mandatory breaths are delivered by a ventilator. A spontaneous breath is one in which inspiration is both triggered (initiated) and cycled (terminated) by the patient, while a mandatory breath is one in which inspiration is either triggered and/or cycled by the ventilator.^{7,8,11} A mandatory breath is described as assisted if it is patient triggered.¹¹ In addition, a spontaneous breath is described as supported if the airway pressure during inspiration rises above baseline pressure. This is commonly seen in the pressure support mode where airway pressure rises to a preselected level above PEEP.^{7,11} Alternatively, a spontaneous breath is described as unassisted if the airway pressure during inspiration does not rise above baseline as is seen in the continuous positive airway pressure (CPAP) setting.⁷

Three breath sequences have been described in the literature and they include the following:^{7,10,11,14}

- Continuous spontaneous ventilation in which all breaths are spontaneous.
- Intermittent mandatory ventilation (IMV) in which mandatory (machine-triggered) breaths are delivered with spontaneous breaths permitted in between. If the mandatory breath is patient triggered, it is referred to as SIMV.
- Continuous mandatory ventilation (CMV) in which all breaths are mandatory, but may be patient or machine triggered. No spontaneous breaths are permitted between mandatory breaths. This is also referred to as controlled mechanical ventilation.

Targeting Schemes

Targeting schemes are the feedback control system by which a ventilator delivers a specific ventilatory

pattern, that is, it represents the relationship between operator inputs and ventilator outputs to obtain a specific ventilator pattern.^{1,15} Output (eg, airway pressure generated) is used as a feedback signal that is compared to operator-set input (eg, preset inspiratory pressure) to change the characteristics of the delivered breath.⁷ It comprises the ventilator settings and programming that determine the ventilator's response to the patient's lung compliance, airway resistance, and respiratory effort.¹⁰

There are two types of control systems, namely, open-loop control and closed-loop control.¹⁶ The open-loop control scheme is the simplest type of control. It is unable to correct for variations such as changes in the patient's ventilatory drive, respiratory system mechanics, or leaks. The information available from the ventilator is not utilized to the advantage of the patient in a meaningful way.¹⁶ The closed-loop control is used in all modern ventilators. It is also called the feedback control. The closed-loop control is used to keep pressure and flow waveforms consistent in the midst of altering patient/system conditions.^{7,16}

There are, at present, seven fundamental targeting schemes used as feedback control loops (ie, closed-loop systems) to create a varying number of ventilator modes.^{1,7,15} With set-point targeting, specific target parameters are set such as V_T or inspiratory flow in volume-control (VC) mode or inspiratory pressure in PC, and the ventilator attempts to deliver them. The goal is to perpetuate a constant output to match a constant input. Set-point targeting is the least complex of the targeting schemes and assumes constant respiratory system mechanics. This is seen in assist-control (AC) modes.^{1,7,15,16} Dual targeting occurs when a ventilator can automatically switch between VC and PC (or vice versa) during a single inspiration based on attaining certain preset parameters such as V_T . It can adapt to changing patient conditions and guarantees either a preset V_T or peak inspiratory pressure (PIP).¹ This is seen in volume-assured pressure support (VAPS).^{1,7,15,16} Servo control is a targeting scheme in which the output of the ventilator, such as pressure, volume or flow, automatically follows a varying input. The ventilator support is proportional to the patient's inspiratory effort. Examples include proportional assist ventilation (PAV), automatic tube compensation, and neurally

adjusted ventilatory assist (NAVA).^{1,7,15,16} Biovariable targeting occurs when a ventilator automatically modifies the inspiratory pressure or V_T in a random manner thereby simulating the biologically variable ventilation seen during normal breathing.¹ This is seen with variable pressure support.¹ Adaptive targeting occurs when a ventilator automatically sets one or more targets between breaths to adjust to varying patient conditions.^{1,7,15} This is automatic adjustment of one set point is to perpetuate a different operator-selected set point, such as adjusting the pressure limit of a breath so as to meet an operator-set V_T target over several breaths.¹⁶ This is seen with pressure-regulated volume control (PRVC).^{1,7,15,16} Optimal targeting is a form of adaptive targeting schemes that enables a ventilator to set both volume and pressure set points, thereby enabling adjustment to varying patient conditions.^{7,15,16} It occurs when a ventilator automatically modifies the targets of the ventilatory pattern to either minimize or maximize some overall performance characteristic. Once an operator has set a target percentage minute volume, it enables the ventilator to make all subsequent adjustments in response to respiratory-system mechanics and patient effort.^{15,16} An example of this is the adaptive support ventilation (ASV).^{1,7,15} Intelligent targeting is another form of adaptive targeting schemes that uses artificial-intelligence techniques, such as rule-based expert systems, fuzzy logic, and artificial neural networks, and is also able to adjust to varying patient conditions.^{1,7} There are limited randomized control trials evaluating the use of advanced targeting schemes, and superiority has not been clearly demonstrated. A myriad of commercially available ventilator mode names exist, majority of which are not particularly different modes. Understanding this is essential in appropriately utilizing the right ventilator mode for optimal patient care that would promote safety, comfort, and eventually liberation.

CLASSIFICATION OF MECHANICAL VENTILATION

Modes of Mechanical Ventilation

A ventilator mode describes the manner in which a breath is delivered to a patient in order to meet physiological demands.⁷ It has been proposed that a

ventilator mode can be classified by specifying the control variable, breath sequence, and targeting scheme.^{7,10} It incorporates variables that control, initiate, sustain, and terminate the breath (phase variables) as well as determine if a change in breath pattern is needed (conditional variables). The emergence of a new generation of microprocessor-based ventilators has resulted in advancements in triggering, monitoring, and safety at the cost of added complexity and expense.^{4,17,18} None of these newer modes of have been shown to reduce morbidity or mortality.^{4,17,18} Following are some of the common conventional and alternative modes of ventilatory support utilized in clinical practice (Table 18–3).

Conventional Modes of Ventilatory Support

Continuous Mandatory Ventilation

In the CMV mode, all breaths are mandatory and delivered by the ventilator at a predetermined frequency and inspiratory time (Figure 18–2). The breaths could either be volume or pressure targeted (or controlled), triggered by the ventilator (ie, time triggered), pressure, volume or flow limited, and time, flow, pressure, or volume cycled by the ventilator.^{19,20} Patients receiving this mode usually require deep sedation or paralysis, or do not have ventilatory drive.¹⁹ Most modern ventilators do not prevent patients from triggering a breath; therefore, this mode has been replaced by the A/C mode.¹⁹ In some ventilator brands, CMV and A/C modes are the same.

Assist-Control Ventilation

In assist-control ventilation (ACV) mode, breaths are mandatory and delivered by the ventilator at a predetermined minimum frequency. The breaths could be volume or pressure targeted (A/C VC or A/C PC), and are either ventilator, that is, time triggered based on a set rate, or patient triggered (using flow or pressure) depending on patient effort and set sensitivity (Figure 18–3). In this mode, assisted breaths (mandatory breaths that are patient triggered) can be delivered at the predetermined pressure or volume in between the ventilator triggered breaths. Similar to CMV, the breaths are also pressure, volume or flow limited and flow, volume, pressure, or time cycled by the ventilator.²⁰ ACV is the preferred mode in most clinical settings, but common problems encountered include respiratory

alkalosis in patients with a high respiratory drive, increased WOB by patients if the sensitivity and flow rates are inadequately set and dyssynchrony in awake patients.^{19,21}

Intermittent Mandatory Ventilation and Synchronized Intermittent Mandatory Ventilation

In the IMV mode, breaths are mandatory and delivered by the ventilator at a set frequency, and are either volume or pressure targeted. Furthermore, the mandatory breaths are triggered and cycled by the ventilator. In between the mandatory breaths delivered, a patient can breathe spontaneously at a frequency and V_T determined by the patient, irrespective of the set ventilator frequency. These spontaneous breaths are patient triggered and patient cycled, and may be augmented by pressure support.^{22–26} Nevertheless, the lack of coordination between spontaneous and mandatory breaths can result in breath stacking if a mandatory breath is triggered before the patient completely exhales a spontaneous breath. The SIMV mode (Figure 18–4) is a form of IMV in which mandatory breaths are delivered at a preset frequency with the patient taking spontaneous breaths in between. However, if the ventilator detects patient effort at the time a mandatory breath is to be triggered, the mandatory breath is delivered in coordination (ie, synchronized) with the patient's effort, that is, it becomes patient triggered instead of ventilator triggered.¹⁹ If no inspiratory effort is detected from the patient within a set interval (ie, synchronization window) at the time scheduled for a mandatory breath, then the ventilator will deliver a time triggered mandatory breath. Modern day ventilators provide SIMV rather than IMV. This mode of ventilation has been used for both primary support as well as weaning from mechanical ventilation, though there is evidence suggesting that its use as a weaning mode may contribute to prolonged weaning time.¹⁷ Additionally, the premise that mandatory breaths of SIMV allow respiratory muscles to rest has been questioned.^{27,28} It is felt that since the respiratory center does not anticipate when the ventilator will deliver the next breath, it continues to provide its output and stimulate respiratory muscle activity even during mechanically generated or supported

TABLE 18–3 Commonly used ventilator modes.

Ventilator Modes	Description	Proprietary Name
Conventional Modes of Ventilation		
CMV	All breaths are mandatory and delivered at a predetermined frequency and inspiratory time. Ventilator triggers all breaths. Patients usually require deep sedation or paralysis, or do not have ventilatory drive. This mode has been replaced by the assist-control mode.	CMV-VC, CMV-PC
ACV	All breaths are mandatory and delivered at a predetermined minimum frequency. Breaths could be triggered by ventilator or patient. Preferred mode for primary support in most clinical settings.	A/C VC, A/C PC
IMV	Breaths are mandatory and delivered by the ventilator at a preset frequency. Mandatory breaths are triggered by the ventilator. In between mandatory breaths, patient can breathe spontaneously.	IMV-VC, IMV-PC
SIMV	Is a form of IMV but differs by ventilator's ability to detect patient effort during preset intervals and delivering a mandatory breath is in coordination with (ie, synchronized) patient's effort. If no effort detected, ventilator will deliver a mandatory breath at the scheduled time (ie, time triggered). SIMV has replaced IMV in clinical practice. Used for primary support and weaning.	SIMV-VC, SIMV-PC
PSV	All breaths are spontaneous. Patient determines the respiratory rate, inspiratory time, and V_T . Patient-ventilator synchrony is enhanced. Used commonly as a weaning mode but can also be used for primary support or in combination with other modes such as SIMV.	Pressure support
Dual-Control Modes of Ventilation		
Dual control	Pressure or volume delivered is controlled by the ventilator via a feedback loop. Ventilator regulation of the pressure or volume occurs within a breath, ie, intrabreath. V_T is guaranteed by switching between PSV and VC. Breaths may be triggered by patient or ventilator.	VAPS or PA
	Pressure or volume delivered is controlled by the ventilator via a feedback loop. Ventilator regulation of the pressure or volume occurs breath to breath, ie, interbreath. V_T is guaranteed by adjusting PS level. Breaths are all patient-triggered.	VS or VPS
	Pressure or volume delivered is controlled by the ventilator via a feedback loop. Ventilator regulation of the pressure or volume occurs breath to breath, ie, interbreath. V_T is guaranteed by adjusting PC. Breaths may be triggered by patient or ventilator.	PRVC, APV, Autoflow, VPC or VCV+
	Combines dual-control, breath-to-breath, time-cycled (mandatory), and flow-cycled (spontaneous) breaths into a single mode. Can switch between PRVC and VS, or PC and PS, or VC and VS. Breaths may be triggered by patient or ventilator.	AutoMode
	Combines dual-control, breath-to-breath, time-cycled (mandatory), and flow-cycled (spontaneous) breaths into a single mode. Ventilator chooses ventilator parameter based on clinician input of IBW and percent minute volume to meet minute ventilation target while minimizing WOB. Can switch between APC and PS, and SIMV-PC and PS. Breaths may be triggered by patient or ventilator.	ASV

(Continued)

TABLE 18–3 Commonly used ventilator modes. (Continued)

Ventilator Modes	Description	Proprietary Name
Nonconventional Modes of Ventilation		
APRV	Uses 2 levels of continuous airway pressure, high and low, with intermittent release to the lower level. Patients are able to take spontaneous breaths during any phase of the respiratory cycle. It is commonly used as an alternative modality in ARDS patients.	APRV
PAV	Continuous spontaneous ventilation in which pressure generated is proportional to patient’s inspiratory effort (volume and flow). It enhances patient-ventilator synchrony.	PAV
NAVA	Continuous spontaneous ventilation in which pressure generated is proportional to the electrical activity of the diaphragm. It enhances patient-ventilator synchrony.	NAVA
HFV	Generates very small tidal volumes with respiratory rates > 100/min. Has been used in patients with ARDS.	HFOV
	Generates very small tidal volumes with respiratory rates > 100/min. Has been used in patients with ARDS, bronchopleural fistulas, burns with significant airway secretions, and patients with raised ICP.	HFPV

A/C, assist control; ACV, assist control ventilation; APV, adaptive pressure ventilation; ARDS, acute respiratory distress syndrome; APRV, airway pressure release ventilation; ASV, adaptive support ventilation; CMV, continuous mandatory ventilation; HFOV, high-frequency oscillatory ventilation; HFPV, high-frequency percussive ventilation; HFV, high-frequency ventilation; ICP, intracranial pressure; IMV, intermittent mandatory ventilation; NAVA, neurally adjusted ventilatory assist; PA, pressure augmentation; PAV, proportional assist ventilation; PC, pressure control; PS, pressure support; PSV, pressure support ventilation; SIMV, synchronized intermittent mandatory ventilation; VAPS, volume assured pressure support; VC, volume control; VCV, volume control ventilation; VPC, variable pressure control; VPS, variable pressure support; VS, volume support; V_T , tidal volume.

FIGURE 18–2 Continuous mechanical ventilation (CMV) using pressure-controlled breaths. All the breaths are triggered by the ventilator as depicted by the absence of a negative deflection on the pressure waveform (top waveform), flow limited (middle waveform), and time cycled. The bottom waveform shows the tidal volume that is being generated, which can be variable based on changes in the patient’s compliance and resistance.

FIGURE 18–3 Assist control ventilation (ACV) using volume-controlled breaths. Some breaths are patient-triggered (depicted by the negative deflection on the pressure waveform [top waveform]), that is, assisted, and some breaths are ventilator-triggered (depicted by the absence of a negative deflection on the pressure waveform [top waveform]), that is, mandatory. The pressure generated can be variable based on changes in the patient’s compliance and resistance, while the flow (middle waveform) and volume (bottom waveform) remain constant.

FIGURE 18-4 Synchronized intermittent mechanical ventilation (SIMV) showing both volume-controlled mandatory breaths triggered by the ventilator at a set frequency and spontaneous pressure supported breaths triggered by the patient in between the mandatory breaths.

breaths. Hence, the patient ends up performing as much WOB in spontaneous as in ventilator generated or supported breaths.

Pressure Support Ventilation

Pressure support ventilation (PSV; [Figure 18-5](#)) is a spontaneous ventilatory mode in which a patient's inspiratory effort is assisted by the ventilator up to a predetermined inspiratory pressure level. Each breath is patient triggered, pressure limited, and flow cycled, thus the patient determines the frequency, inspiratory time and V_T and thereby

FIGURE 18-5 Pressure support ventilation (PSV) in which all breaths are spontaneous and the patient's inspiratory effort is assisted by the ventilator up to a predetermined inspiratory pressure level. Each breath is patient triggered, pressure limited, and flow cycled; thus the patient determines the respiratory frequency, inspiratory time, and tidal volume.

patient-ventilator synchrony is enhanced.^{26,29,30} This mode is often confused with PC ventilation which is patient or ventilator triggered, pressure limited, and time cycled ([Figure 18-2](#)). Inspiration in PSV ceases when the peak inspiratory flow rate decreases to a predetermined minimum level (eg, 5 L/min) or a percentage of the initial inspiratory flow (eg, 25%).^{19,31} The WOB related to this mode is a function of the selected pressure level, such that higher levels provide more ventilatory support and decrease the workload of the respiratory muscles.¹⁹ This is used commonly as a weaning mode, but can also be used for primary support or in combination with other modes, such as SIMV.^{29,31} It should not be used in patients with unstable respiratory drive.

Alternative Modes of Ventilatory Support

Changes in ventilatory support continue to occur as a result of microprocessor control of mechanical ventilators. This has led to the production of devices that are increasingly more complex. Some of the more common alternative modes are described below briefly.

Dual Control Modes

Dual control is a mode of ventilation in which the pressure or volume delivered is controlled by the ventilator via a feedback loop.³² Ventilator regulation of the pressure or volume could occur within a breath, that is, intrabreath or from breath-to-breath, that is, interbreath. In the former, the ventilator switches from PC to VC during the breath, while in the latter the ventilator functions in either the PS or PC mode, adjusting the pressure limit to automatically maintain a predetermined V_T .³²

VAPS or pressure augmentation uses dual control within a single breath. The breath may be patient triggered or ventilator triggered. After a breath is triggered, the ventilator attempts to reach the predetermined pressure target, that is, the PS setting. This portion of the breath is the pressure-limited portion. As the pressure level is attained, the ventilator determines the adequacy of the V_T delivered to the patient by comparing the volume delivered with the predetermined V_T . If the ventilator senses that the desired V_T will not be reached, inspiration continues (ie, increase in inspiratory time [T_I]) according to the set peak flow, whereby the breath

FIGURE 18–6 Volume support (VS) ventilation in which all breaths are triggered by the patient and are pressure supported. A constant tidal volume is maintained by the ventilator by adjusting the pressure support level, that is, variable pressure support.

changes from a pressure limited to a volume limited mode. This assures the predetermined volume is delivered to the patient.^{19,32} However, if the delivered V_T and predetermined V_T are the same, the breath remains in the PS mode and is flow cycled. Consequently, VAPS combines the high initial flow of a pressure-limited breath with the constant volume delivery of a volume-limited breath.

Volume support ventilation (VS) or variable pressure support ventilation uses dual control from breath-to-breath (Figure 18–6). The breaths are pressure-limited and flow-cycled and are all triggered by the patient.¹⁹ The ventilator maintains V_T by adjusting the PS, that is, V_T is used as a feedback control for continuously adjusting the pressure support level for the next breath.³³ Because all breaths are PS breaths, cycling occurs when the flow falls less than 25% of peak value.³³ It is a combination of the positive attributes of PSV with the constant minute volume and V_T seen with volume-controlled ventilation (VCV).

PRVC uses dual control from breath-to-breath (Figure 18–7). It has also been described as adaptive pressure ventilation, autoflow, VCV+, variable pressure control, though small technical differences exist.^{10,33} The breaths are ventilator or patient triggered, pressure limited, and time cycled. In this mode of ventilation, the V_T is used as the feedback control mechanism (conditional variable) for continuously adjusting the pressure limit.^{10,32} Initially, a series of test breaths are delivered to determine the inspiratory pressure required, based on the patient's

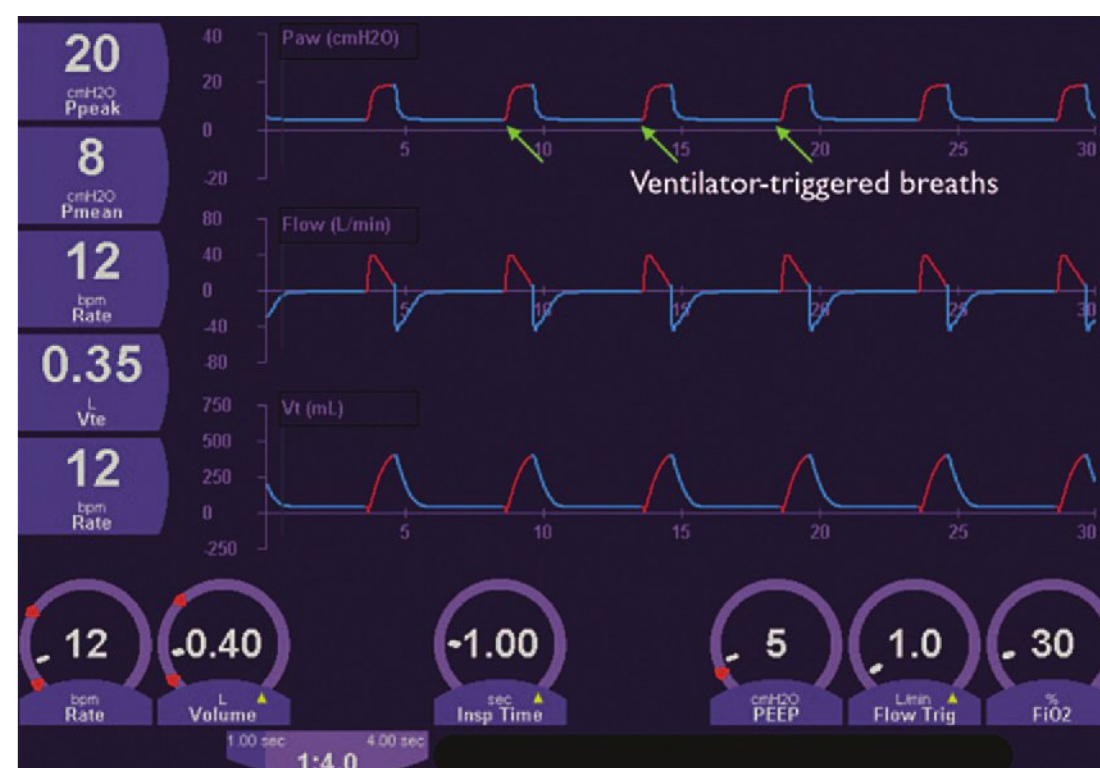

FIGURE 18–7 Pressure-regulated volume control (PRVC) (ie, adaptive pressure ventilation) in which the breaths are currently being triggered by the ventilator and not the patient. The ventilator adjusts the pressure limit based on the patient's respiratory mechanics to guarantee the targeted tidal volume.

respiratory mechanics, to deliver the desired V_T within the chosen T_I .²⁹ This mode maintains a minimum peak pressure which provides a constant predetermined V_T and an automatic reduction of inspiratory pressure as the patient's efforts increase or lung mechanics improve. Conversely, an increase in inspiratory pressure will occur on the next breath if a change in lung mechanics or patient effort causes the V_T delivered to be below the target V_T .^{29,32} A major benefit of this mode is that the ventilator can adjust inspiratory flow according to the patient's demand while maintaining a constant minimum minute volume, thus making this mode more comfortable for the patient. Conversely, the fixed minute ventilation may result in alveolar overdistention in the face of varying compliance of the lung.³⁴

AutoMode ventilation combines dual control breath-to-breath time cycled breaths (PRVC) with dual control breath-to-breath flow-cycled breaths (VS) into a single mode. In this mode, the ventilator is able to switch from either PRVC to VS or vice versa based on whether the breaths are mandatory (time triggered, pressure limited, and time cycled) or spontaneous (patient triggered, pressure limited, and flow cycled). In a similar fashion, this mode can also switch from PS to PC (Figure 18–8) or from VS to VC if the patient is unable to sustain spontaneous breathing and requires mandatory breaths to be delivered.^{32,35}

FIGURE 18–8 AutoMode ventilation combining pressure control and pressure support into a single mode. The ventilator is able to switch from either pressure control to pressure support or vice versa based on whether the breaths are mandatory (time triggered, pressure limited and time cycled) or spontaneous (patient triggered, pressure limited, and flow cycled). If the patient is unable to sustain spontaneous breathing, mandatory breaths are delivered.

Nonconventional Modes of Ventilatory Support

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a pressure limited, time cycled (flow cycled in some ventilator brands) mode (Figure 18–9) that uses a high continuous airway pressure level (P_{high}) with a periodic release to a low continuous airway pressure level (P_{low}).^{36,37} Patients are able to spontaneously breathe in both phases of the ventilator cycle, that is, during P_{high} and P_{low} .³⁶ Time spent at P_{high} (T_{high}) is usually longer than T_I in conventional ventilation, thereby promoting adequate alveolar recruitment and oxygenation. However, the brief periodic expiratory release to P_{low} in addition to the patient's ability to breathe spontaneously allow for adequate ventilation. The V_T generated is a function of the lung compliance, airway resistance, periodicity, and duration of the release phase.³⁸ Recently, several studies and editorials have questioned the usefulness and safety of spontaneous breathing in the setting of ARDS.³⁹

Proportional Assist Ventilation

PAV is a ventilatory mode that amplifies a patient's effort without imposing predetermined targets such as flow or volume.^{40,41} The ventilator applies pressure in proportion to the patient's inspiratory effort.⁴²⁻⁴⁴

FIGURE 18–9 Airway pressure release ventilation (APRV) that is a pressure-limited and time-cycled mode that uses high and low levels of continuous airway pressure with a periodic release between the two. As is seen in this figure, patients are able to spontaneously breathe in both phases of the ventilator cycle that enhances oxygenation and further lung recruitment. However, this capability also increases the risk of producing higher tidal volumes than would be conventionally recommended.

Unlike in PSV where the inspiratory pressure provided by the ventilator is constant, with PAV, the ventilator provides dynamic inspiratory pressure assistance in linear proportion to the patient-generated flow and volume as a result of the pressure generated by the respiratory muscles. The ventilator-applied pressure increases and decreases according to the proportion of the patient's effort and this results in better patient-ventilator synchrony.¹⁹ The ventilator amplifies the patient's instantaneous effort while leaving complete autonomy over the breathing pattern (such as tidal volume, inspiratory and expiratory duration, and flow) to the patient. The proportion of assist provided is determined by the continuous calculation of the resistive and elastic loads and this is amplified to assist the patient.¹⁹ Hence, the system functions by positive feedback (ie, mechanical unloading). In this mode, the proportionality between applied pressure and both flow and volume is selected, and this determines the magnitude of the decrease in both the resistive and elastic loads faced by the inspiratory muscles.

The necessity of the accurate measurements of airway resistance and respiratory system elastance are limitations to the use of PAV. However, the development of PAV with load adjustable gain (PAV+) may have solved this, thereby facilitating broader clinical use.^{45,46}

Adaptive Support Ventilation

ASV is a pressure-targeted closed loop mode of ventilation with optimal targeting schemes for V_T , respiratory rate and \dot{V}_E , in response to changes in respiratory mechanics and spontaneous breathing (Figure 18–10).⁴⁷ The ventilator determines the predicted \dot{V}_E (ie, 0.1 L/kg/min) based on the patient's ideal body weight (IBW) and estimated dead space (ie, 2.2 mL/kg), which represents 100% minute ventilation.^{10,48} The clinician then inputs the target percent of minute ventilation (%MinVol) that the ventilator will support. Subsequently, the ventilator automatically utilizes the Otis' equation to predict a V_T and optimal frequency (f) combination that minimizes the WOB.⁴⁹ The target V_T is calculated as \dot{V}_E/f . If the patient is making respiratory efforts, ASV delivers

FIGURE 18–10 Adaptive support ventilation (ASV). The ventilator determines the predicted minute ventilation (\dot{V}_E) based on the patient's ideal body weight (IBW) that represents 100% minute ventilation and the clinician decides on the target percent of minute ventilation (%MinVol) that the ventilator will support. If the patient makes respiratory efforts, ASV delivers pressure support breaths (patient triggered, pressure targeted, and flow cycled). However, in the absence of respiratory efforts, as in this figure, ASV delivers adaptive pressure-controlled (APC) breaths (ventilator triggered, pressure targeted, and time cycled) so as to maintain the target \dot{V}_E .

PS breaths (patient triggered, pressure targeted, and flow cycled), and can only adjust the inspiratory pressure level and thereby V_T , in order to maintain target \dot{V}_E . However, in the absence of respiratory efforts, ASV delivers adaptive pressure controlled breaths (ventilator triggered, pressure targeted, and time cycled) while still maintaining the target \dot{V}_E by being able to adjust both V_T and f .^{10,47,50} The ventilator will continuously monitor WOB relative to selected %MinVol, by adjusting peak pressure, V_T , and f accordingly. ASV has been used for weaning as it progressively and automatically decreases inspiratory pressure as the patient's respiratory mechanics improve and all breaths remain spontaneous.⁵¹

Neurally Adjusted Ventilatory Assist

NAVA is a ventilator mode whereby positive pressure is applied to the airway opening in proportion to the electrical activity of the diaphragm (EAdi).^{52,53} This diaphragmatic activity is directly related to phrenic nerve impulse. A specially designed esophageal catheter with multiple electrodes is inserted to collect the EAdi.⁵⁴ The use of EAdi to estimate respiratory center output needs the integrity of the respiratory center, phrenic nerve, and neuromuscular junction to be intact, and assumes the diaphragm to be the primary inspiratory muscle. This diaphragmatic electrical activity is picked up by the electrode, and acts as a trigger for a pressure support breath to be delivered by the ventilator (Figure 18–11). The pressure delivered by the ventilator is calculated by multiplying the EAdi by a proportionality factor called "NAVA level" (expressed as cm H₂O/ μ V). Ultimately, the pressure delivered by the ventilator is cycled-off as the EAdi falls to 40% to 70% of the peak EAdi reached during inspiration.^{52,53} NAVA is said to represent the first form of assisted ventilation in which the patient's respiratory center can assume full control of the magnitude and timing of the mechanical support provided, in spite of changes in respiratory drive, mechanics, and muscle function. This results in a better patient-ventilator synchrony, reduction in the risk of iatrogenic hyperinflation, respiratory alkalosis, and hemodynamic impairment.^{52,53}

High-Frequency Ventilation

High-frequency ventilation (HFV) is a mechanical ventilatory technique that uses respiratory rates

FIGURE 18–11 Neurally adjusted ventilatory assist (NAVA) in which positive pressure is delivered in proportion to the electrical activation of the diaphragm (EAdi). Ventilatory support begins when the neural drive to the diaphragm starts to increase, such that as the EAdi progressively rises, inspiratory airway pressure also rises proportionally. The pressure delivered is reached by multiplying the EAdi by a proportionality factor called “NAVA level” (in this patient: 1.6 cm H₂O/μV). The pressure delivered by the ventilator is cycled-off as the EAdi is terminated by the respiratory centers.

greater than 100 breaths/min along with the generation of small V_T , that are smaller than traditional estimations of both anatomic and physiologic dead space and range from approximately 1 to 5 mL/kg.^{55,56} Three types of HFV exist, but the two types discussed are high-frequency oscillatory ventilation (HFOV) and high-frequency percussive ventilation (HFPV) whose waveforms are shown in [Figure 18–12](#). In contrast to conventional ventilation where gas transport takes place by bulk delivery of gas, further theoretical mechanisms believed to enhance gas exchange in these forms of HFV have been described in the literature and include asymmetric velocity profiles, longitudinal (Taylor) dispersion, pendelluf, cardiogenic mixing, and molecular diffusion.^{55,57,58} There has been interest in the use of HFV in severe hypoxemic respiratory failure, however, studies have failed to demonstrate mortality benefit in adult patients.

HFOV is characterized by the generation of small V_T as a result of the oscillation of a bias gas flow that result in pressure swings within the airway at frequencies ranging from 3 to 15 Hz (usually 3–6 Hz in adults). These pressure swings may be significant proximally, but become attenuated as they reach the distal airways and alveoli resulting

FIGURE 18–12 The waveforms that can be generated in high-frequency oscillatory ventilation (HFOV) versus high-frequency percussive ventilation (HFPV). With HFPV, small volumes are delivered in a stepwise manner with scheduled interruptions that result in the formation of high- and low-frequency cycles. It has crudely been described as an amalgam of HFOV and pressure-controlled breaths into one.

in the low V_T . The oscillations are produced by an oscillatory diaphragm/piston pump, and result in an active inspiratory and expiratory phase. The rapid oscillations of gas are delivered at pressures above and below a constant mean airway pressure (mPaw), which in addition to the fraction of inspired oxygen (FIO₂), determine the level of oxygenation. Ventilation, on the other hand, is directly related to the pressure amplitude of oscillation (ΔP); that is, degree of displacement by the oscillatory diaphragm/piston pump, but inversely related to the set frequency.⁵⁹ The combined effects of a high mPaw and small V_T potentially result in improved recruitment of alveoli and gas exchange with an associated reduced risk of overdistention.^{60–62} Because of the low V_T generated, it is considered to be lung protective. It has been used primarily in patients with ARDS in whom conventional ventilatory strategies have failed. However, recent trials have demonstrated that it has limited benefit for the treatment of these patients.^{63,64}

HFPV is a pressure-limited, flow-regulated, and time-cycled ventilator mode that delivers a series of high-frequency (200–900 cycles/min) small volumes in a consecutive stepwise stacking manner resulting in the formation of low-frequency (4–30 cycles/min) convective pressure-limited breathing cycles ([Figure 18–13](#)).^{62,65–67} Gas exchange is a function of the

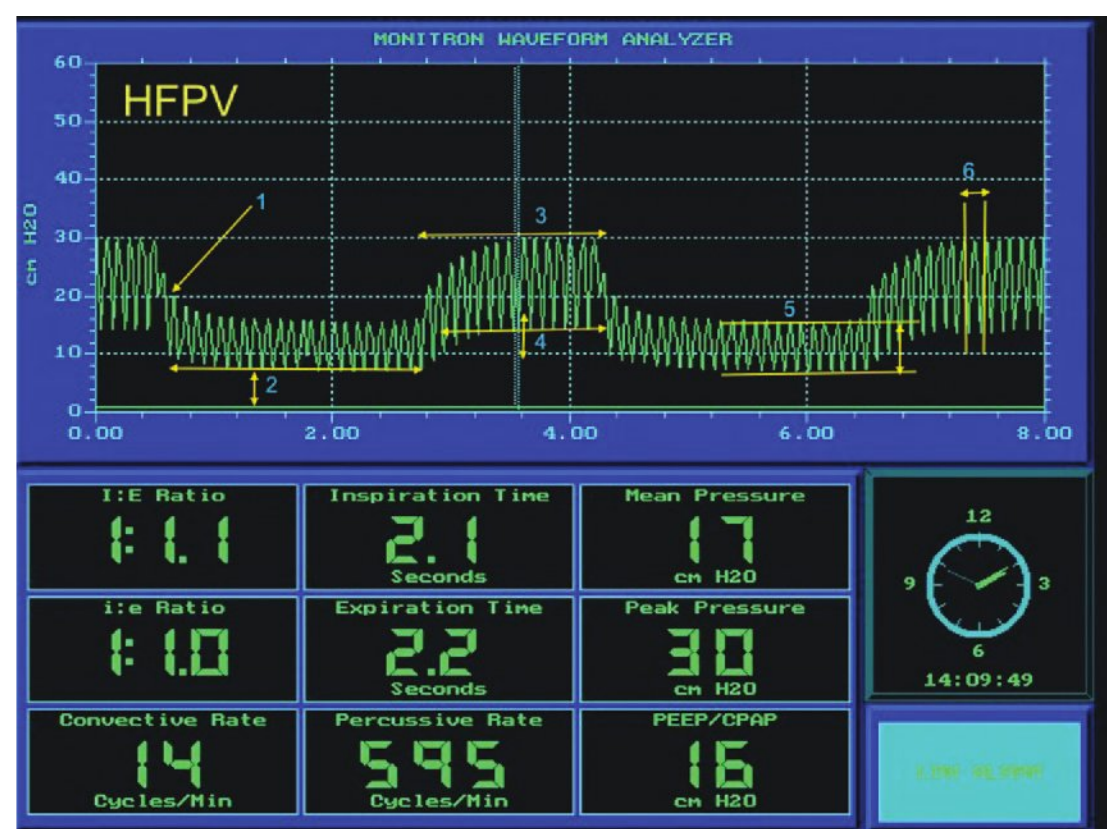

FIGURE 18–13 High-frequency percussive ventilation in which the breaths are pressure-limited, flow-regulated, and time-cycled, but are delivered at a high frequency (in this case 655 cycles/min) with very small volumes. These volumes are delivered in a consecutive stepwise stacking manner resulting in the formation of low-frequency (in this case 14 cycles/min) convective pressure-limited breathing cycles. Gas exchange is a function of the percussion frequency. The interplay of its control variables plays a role in determining the mPaw and degree of gas exchange. 1. Periodic scheduled interruptions signifying end of inspiration and onset of expiration. 2. Demand continuous positive airway pressure (CPAP). 3. Pulsatile flow during inspiration at 595 cycles/min. 4. Convective pressure-limited breath with low-frequency-cycle at 14 cycles/min. 5. Oscillatory CPAP. 6. Single percussive breath.

percussion frequency, such that at average percussion frequencies (500–600 cycles/min) oxygenation and ventilation are augmented, while low percussion frequencies less than 500 cycles/min may be utilized in patients with deep-seated secretions so as to enhance clearance.^{62,67–69} The interplay of its control variables (ie, inspiratory and expiratory time, percussion frequency, PIP, pulsatile flow rate, and PEEP) either individually or in combination, play a role in determining the mPaw and degree of gas exchange.^{62,67,69} HFPV has been used as a rescue modality in patients with severe hypoxemic respiratory failure, such as those with ARDS in whom conventional ventilatory strategies have failed. It has also been used in patients who tend to have a significant amount of airway secretions and debris because of its pulsatile flow mechanism. There is a paucity of literature with regards to its use and it has not been demonstrated to bring about a reduction in mortality.

Adjuncts to Mechanical Ventilation

Nonventilatory strategies that have been used in conjunction with mechanical ventilation either to enhance oxygenation, patient comfort or maintain other goals of mechanical ventilation, include prone positioning, extracorporeal membrane oxygenation also called extracorporeal life support, use of neuromuscular blocking agents or inhaled vasodilators.^{70–75}

MONITORING DURING MECHANICAL VENTILATION

Pulmonary mechanics are usually assessed during mechanical ventilation. It is essential for monitoring the course of the pulmonary disease, providing adequate ventilatory support while minimizing iatrogenic effects, and determining time of discontinuation from mechanical ventilation.⁷⁶ The rapid airway occlusion technique is the most commonly used method for measuring pulmonary mechanics.^{77,78}

Measurement of Peak and Plateau Pressures

Measurement of peak (PIP) and plateau (Pplat) pressures (Figure 18–14) can give valuable information regarding the patient's airways (resistance) and the respiratory system compliance. It is recommended that these pressures be measured regularly, especially when there is a change in the patient's condition. In a mechanically ventilated patient, the ventilator tubing is connected via the endotracheal tube to the patient's airways. These components are responsible for the resistive properties of the respiratory system. The lungs and chest wall are responsible for the elastic properties of the respiratory system (Figure 18–15a).⁷⁹ When a breath is delivered to the patient, the patient and the ventilator have to overcome the airways resistance and the respiratory system elastance. At the end of delivery of the V_T , the maximum pressure is recorded. This is the PIP (Figure 18–15b),⁷⁹ and it reflects the pressure that has to be developed to overcome the airway resistance and to expand the lungs and chest wall, that is, PIP reflects airways resistance + respiratory system compliance. At the end of inspiration, when an end-inspiratory pause is introduced, a newer lower pressure is reached. This is called the Pplat (Figure 15c).⁷⁹ The plat is measured in a no flow state. Since airways

FIGURE 18–14 Graphical representation of the peak inspiratory pressure (PIP) and the plateau pressure (Pplat). The PIP is the maximum airway pressure measured at the end of inspiration and it represents the pressure required to overcome the elastic and resistive forces of the respiratory system. The application of a rapid end-inspiratory occlusion in a passively ventilated patient results in the interruption of constant gas flow with a subsequent rapid drop from PIP to Pplat, which represents the compliance of the lung. The difference between PIP and Pplat represents the pressure lost in overcoming the resistance to the flow of gas within the airways. Elevations in PIP or both PIP and Pplat assists in determining whether the patient is having primarily an airway problem versus a compliance problem.

resistance is flow dependent, it (airways resistance) will be 0 cm H₂O/L/s in a no flow state. Thus, the Pplat reflects only the state of respiratory system compliance (C_{RS}), that is, Pplat is proportional to C_{RS} and is expressed as⁷⁶:

$$C_{RS} = V_T / (P_{plat} - \text{Total PEEP})$$

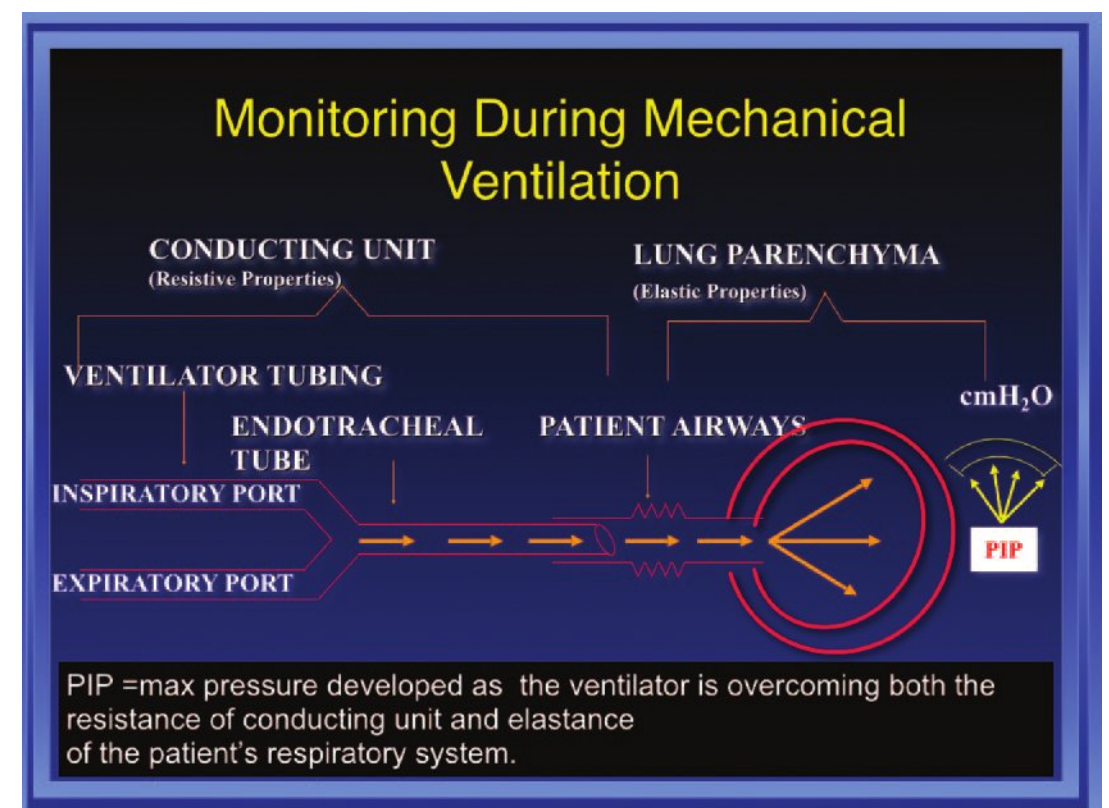

Furthermore, $PIP - P_{plat}$ reflects airway resistance. Airway resistance (R_I) during inspiration can be expressed as^{76,80}:

$$R_I = (PIP - P_{plat}) / \dot{V}_I$$

where \dot{V}_I is inspiratory flow.

The clinical applications of these pressure measurements are tabulated in [Table 18–4](#).

With the placement of an esophageal balloon manometer in a passively ventilated patient, the direct measurement of esophageal pressure (P_{ES} ; [Figure 18–16](#)) can occur and this is used as a surrogate for pleural pressure (P_{PL}). As a result, the true distending pressure across the lungs, that is, the transpulmonary pressure (P_{TP}), expressed as the difference between the alveolar pressure and pleural

TABLE 18–4 Applications of peak and plateau pressures.

Clinical Condition	PIP	Pplat	Finding
Deterioration of respiratory status	High	Normal	Airway resistance problem
Deterioration of respiratory status	High	Elevated	Respiratory system elastance problem from the lung (pulmonary edema, pneumothorax, ARDS, lung contusion), chest wall or abdominal compartment (obesity, ascites, chest wall deformities) or both
Deterioration of respiratory status	High	Elevated	Determination of the pleural pressure may assist in determining the transpulmonary pressure in cases where Pplat may be falsely elevated
Determination of pressure support level	—	—	Equal to PIP-Pplat to overcome airways resistance
ARDS patients	—	< 30 cm	Keep Pplat pressures below 30 cm H ₂ O

ARDS, acute respiratory distress syndrome; PIP, peak inspiratory pressure; Pplat, plateau pressure.

pressure ($P_{ALV} - P_{PL}$), may be obtained. T is useful in cases where elevated abdominal pressures such as in obesity, ascites, or abdominal compartment syndrome, may falsely elevate the Pplat.

Intrinsic PEEP

It is important to clarify the following terms with regards to PEEP, namely, intrinsic PEEP (PEEP_i or auto-PEEP), extrinsic PEEP (or set PEEP) and total PEEP. At end exhalation in a passively ventilated patient, airway pressure (P_{AW}) may be equal to atmospheric pressure (P_{ATM}) or may be raised to a level commensurate with the applied PEEP.⁸¹ When an end-expiratory pause maneuver is performed causing airflow to cease and equilibration to occur

FIGURE 18–16 This figure shows how placing an esophageal probe to determine esophageal pressure (surrogate for pleural pressure) can provide accurate measurements of the transpulmonary pressure, that is, the distending pressure within the lungs. This assists in managing patients who may have conditions causing elevated pleural pressures, for example, pleural effusion, morbid obesity, ascites, etc, that would result in an elevated plateau pressure and thereby limit the amount of PEEP that may be administered to enhance their oxygenation or recruit the lungs.

between end-expiratory pressure and proximal P_{AW} , the pressure measured is referred to as total PEEP.⁸² Intrinsic PEEP is the difference between the total PEEP and extrinsic PEEP. Common features that suggest the presence of PEEP_i include the presence of flow at end expiration (Figure 18–17), if end-expiratory pause pressure exceeds the externally applied PEEP (ie, extrinsic PEEP), and if the addition of extrinsic PEEP does not raise the PIP. T is commonly seen in situations of dynamic hyperinflation and active breathing efforts in which hemodynamic compromise, increased WOB (Figure 18–18), and barotrauma can result.⁸²

Work of Breathing

Work is performed by the ventilator to overcome the elastic and frictional resistances of the lungs and chest wall during mechanical ventilation. Factors that may affect the WOB in mechanically ventilated patients include compliance, resistance, PEEP_i (Figure 18–18), endotracheal tube diameter, V_T , and minute ventilation.⁷⁸ WOB is not commonly calculated in clinical practice, and its use has not been shown to be superior to simpler and more commonly used measurements such as PIP, Pplat, or PEEP_i.⁷⁸

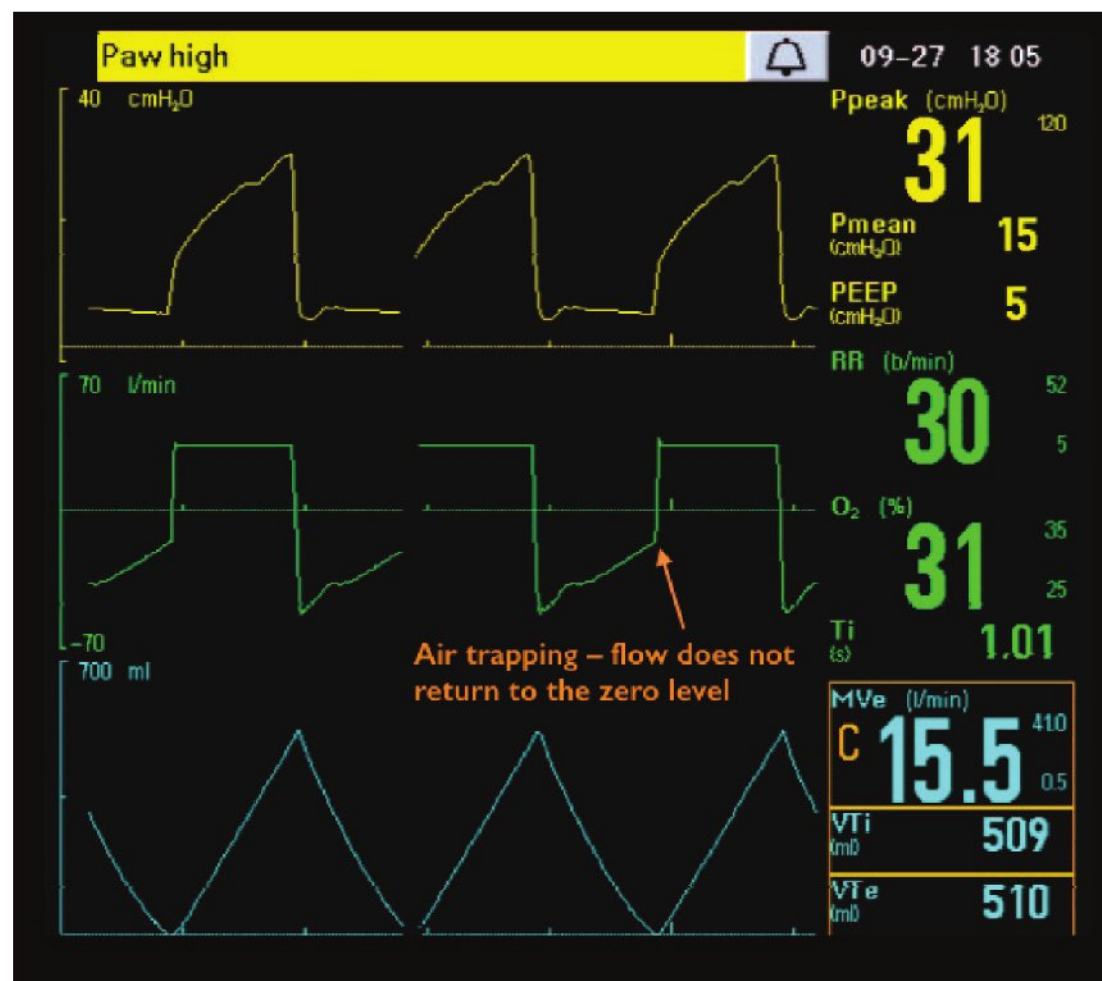

FIGURE 18–17 This figure shows how intrinsic positive end-expiratory pressure (PEEP_i) can be revealed on the flow waveform as a result of air trapping. This is seen as the expiratory limb does not return back to baseline at the end of exhalation. This can be further confirmed by performing an end-expiratory pause maneuver. It is seen in situations of dynamic hyperinflation and active breathing efforts, resulting in hemodynamic compromise, increased work of breathing, and barotrauma.

MECHANICAL VENTILATION IN SPECIFIC CONDITIONS

The choice of which ventilator mode and what settings to be used may be influenced by the patient's underlying condition. Nevertheless, the goals of mechanical ventilation in such situations must be maintained.¹⁻³ Ventilatory management in some common conditions are presented in [Table 18–5](#).⁸³⁻⁸⁸

Ventilatory Support in Severe Hypoxemic Respiratory Failure

It is imperative to institute the Acute Respiratory Management in ARDS (ARMA) guidelines in all patients with ARDS.⁸³ After instituting a lung protective strategy (low V_T , low stretch), the patient should receive a V_T of 6 mL/kg IBW. After ensuring that the patient is breathing synchronously with the ventilator, the Pplat is checked. If the Pplat is more than 30 cm H₂O, the V_T is lowered gradually to 4 mL/kg IBW. After stabilizing the patient more than 12 to 24 hours and instituting PEEP, the

FIGURE 18–18 This figure shows how a patient's work of breathing can increase as a result of the development of intrinsic positive end-expiratory pressure (PEEP_i). The patient now has to generate 6 cm H₂O instead of 1 cm H₂O of negative pressure to open the inspiratory demand valve as a result of the development of 5 cm H₂O of PEEP_i. (Reproduced with permission from Raoof S, Khan F: Mechanical Ventilation Manual. Philadelphia: American College of Physicians; 1998.)

PaO_2/FIO_2 (P/F) ratio is checked. If the P/F ratio is 100 or less, the patient falls into the severe ARDS category, as defined by the Berlin criteria.⁸⁹ The mortality in these patients is an average of 52% (range 36–68%). This is in contrast to those who show an improvement in their P/F ratio (> 200) within 24 hours after institution of lung protective strategies. Their mortality ranges from 12.5% to 23%.^{90,91} Other variables that define severe ARDS include⁶² high ventilatory requirements as demonstrated by $FIO_2 \geq 0.7$ or PEEP >15 cm H₂O or inability to maintain Pplat less than 30 cm H₂O on V_T 4 mL/kg IBW or oxygenation index more than 30. In these individuals, rescue therapy may be considered. A review of the published literature regarding rescue therapies indicates the following: (a) there is very limited data to show that these rescue therapies reduce mortality; (b) most of these therapies result in improvement in oxygenation, especially in the subset of patients who show recruitment with the application of higher PEEP; (c) improvement of oxygenation does not translate to reduction in mortality; (d) the window period to use these rescue therapies is limited to 72 to 96 hours; (e) if instituted late, conventional mechanical ventilation has inflicted ventilator-induced lung injury leaving very little recruitable lung; and (f) the choice of recruitment strategies is based upon their availability, and the familiarity of the treating team with these modes.

The data regarding individual modalities used as rescue therapy are shown in [Table 18–6](#).

COMPLICATIONS OF MECHANICAL VENTILATION

Although in many clinical situations mechanical ventilatory support can be life-saving, it is commonly associated with many complications. The goal is always to prevent iatrogenic injury; however, avoiding these untoward events may not always be achievable. It is, therefore, important to promptly recognize and address these complications as it may be life-saving. [Table 18–7](#) lists the common pulmonary and extra-pulmonary complications that have been associated with mechanical ventilation.^{19,92–99}

DISCONTINUATION OF MECHANICAL VENTILATION

As stated earlier, one of the goals of mechanical ventilation is to promote liberation from it as quickly and as safely as possible. Once the inciting event or condition that resulted in mechanical ventilation begins to resolve, the focus should be on discontinuation so as not to expose the patient to potential complications ([Table 18–7](#)). Weaning has been used synonymously with discontinuation from mechanical ventilation; however, weaning is the systematic method of gradually decreasing the ventilatory support level as tolerated.¹⁰⁰ This can result in unnecessary prolongation of ventilatory support in those who no longer require it.

Current evidence-based guidelines focus attention on establishing readiness for a spontaneous

TABLE 18–6 Strategies used in rescue therapy.

Modality	Data Supporting Use
Higher levels of PEEP than used in ARMA trial ¹¹³⁻¹¹⁵	No reduction in mortality based on 3 articles listed. However, if recruiters are identified by recruitment trials, it is possible that this subgroup may experience greater benefit than harm.
Lung recruitment maneuvers ¹¹²	Not routinely recommended. Desaturation and hypotension are seen in 22% of patients, although serious complications such as air leak are uncommon.
Prone position ⁷⁵	Recent data indicate that patients with P/F ratio < 100, who are prone early in the course of ARDS, kept prone approximately 75% of the time, in centers that are well versed with proning patients, there is a reduction in 28- and 90-d mortality.
HFOV ^{63,64}	Based on 2 recent trials (OSCILLATE study and OSCAR trial), HFOV cannot be recommended as first mode of therapy for ARDS. It is one of the rescue therapies that have not shown reduced mortality when compared with conventional lung protective strategies. In fact, in the OSCILLATE study, using an aggressive strategy with high mean airway pressures, more hemodynamic compromise, larger number of organ failure, and higher mortality was noted.
APRV ¹¹¹	Should be used with caution. Very few studies have shown survival benefits.
ECMO/ECLS ^{73,74,110}	May be considered in patients at hospitals with this technology available.

APRV, airway pressure release ventilation; ARDS, acute respiratory distress syndrome; ARMA, acute respiratory management in ARDS; ECLS, extra-corporeal life support; ECMO, extracorporeal membrane oxygenation; HFOV, high-frequency oscillatory ventilation; OSCAR trial, high-frequency OSCillation in ARDS; OSCILLATE trial, oscillation for acute respiratory distress syndrome (ARDS) treated early trial; PEEP, positive end-expiratory pressure.

breathing trial (SBT) by clinical assessment of stability or recovery, then carrying out a SBT to determine the potential for ventilator discontinuation, and finally identifying the causes of a failed SBT if it occurs.¹⁰¹ It is essential to properly time the performance of a SBT as premature discontinuation is fraught with its own complications such as airway compromise, muscle overload and fatigue, cardiovascular stress, and impaired gas exchange. Discontinuation of mechanical ventilation is a process that must, therefore, be carried out with proper caution and monitoring.

Contemplating Mechanical Ventilation Discontinuation

A patient should be considered daily for ventilator withdrawal if the following prerequisites are present prior to conducting a SBT¹⁰¹: partial or complete recovery of conditions that resulted in respiratory failure; adequate oxygenation with low PEEP, that is, PaO₂/FIO₂ more than 200, PEEP 8 cm H₂O or less, and FIO₂ 0.5 or less; absence of severe acidosis, that is, pH 7.25 or more; hemodynamic stability with minimal or no vasopressor support; and presence of spontaneous inspiratory effort. Multiple physiological parameters have been investigated as predictors

for successful discontinuation of mechanical ventilation. However, these indices have demonstrated limited value in doing so.¹⁰²

Mechanical Ventilation Discontinuation Assessment

Patients who fulfill the aforementioned prerequisites should undergo a SBT. Regardless of the SBT method used (ie, CPAP of 5 cm H₂O, PSV of 5-7 cm H₂O, or T-piece breathing trial), an initial screening phase of a SBT lasting a few minutes should be performed to assess tolerance of the trial. Tolerance is determined by assessing objective parameters, such as adequacy of gas exchange, hemodynamic stability, ventilatory pattern, and subjective parameters, such as mental status changes, patient discomfort, diaphoresis, and signs of increased WOB. Based on a successful outcome of the initial screen, the SBT should continue for a total duration of 30 to 120 min. To determine SBT success, an integrated assessment of the following parameters should take place¹⁰¹:

- Respiratory pattern—RR less than 35 per minute
- Gas exchange—oxygen saturation more than 90%

TABLE 18–7 Complications associated with mechanical ventilation.

Complication	Clinical Presentation
Upper airway and tracheobronchial tree problems related to intubation	<ul style="list-style-type: none"> • Early problems: trauma, right main stem intubation • Late problems: ulcerations, tracheomalacia, tracheoesophageal fistula, tracheoinnominate fistula
Pulmonary barotrauma resulting from high peak airway pressures and/or underlying disease process	<ul style="list-style-type: none"> • Subcutaneous emphysema, pneumothorax, pneumomediastinum, pneumopericardium, bronchopleural fistula resulting from the placement of a chest tube
Ventilator-induced lung injury	<ul style="list-style-type: none"> • Exposure to high transpulmonary pressures (barotrauma), alveolar overdistension (volutrauma), and/or repetitive opening and closing of the alveoli (atelectrauma) resulting in lung damage, as well as triggering an inflammatory response (biotrauma) that leads to injury to nonpulmonary organs and possible organ failure
Ventilator-associated event	<ul style="list-style-type: none"> • Development of worsening oxygenation after a baseline period of stability or improvement, subsequent development of signs of infection (ie, fever, purulent respiratory secretions, positive cultures), and pneumonia
Ventilator-induced diaphragm dysfunction	<ul style="list-style-type: none"> • Disuse muscle atrophy particularly from prolonged mechanical ventilation, use of ventilation modes that minimize patient effort and overuse of sedative and analgesic agents that decrease respiratory drive, thereby decreasing patient work during assisted breaths
Patient-ventilator dyssynchrony	<ul style="list-style-type: none"> • Can result in hypoxemia, increased work of breathing, hemodynamic compromise, discomfort, and agitation
Oxygen toxicity	<ul style="list-style-type: none"> • Prolonged use of high F_{iO_2} can trigger the release of oxygen-free radicals that can further cause lung damage
Cardiovascular effects	<ul style="list-style-type: none"> • Hemodynamic compromise
Gastrointestinal effects	<ul style="list-style-type: none"> • Stress-related mucosal disease that can lead to gastrointestinal bleeding, motility disturbances, pneumoperitoneum
Renal effects	<ul style="list-style-type: none"> • Renal hypoperfusion leading to decreased urine output and risk of developing renal failure
Neuromuscular effects	<ul style="list-style-type: none"> • Critical illness polyneuropathy and myopathy resulting in limb weakness and flaccidity, respiratory muscle weakness, difficulty in weaning from ventilator

F_{iO_2} , fraction of inspired oxygen.

- Hemodynamic status—systolic blood pressure less than 180 mm Hg, heart rate less than 140 per minute or heart rate change less than 20% from baseline
- Patient comfort—absence of development of anxiety or diaphoresis

Extubation Assessment

Following a successful SBT, there is a high likelihood that a patient may tolerate permanent discontinuation of mechanical ventilation.¹⁰¹ In removing the artificial airway, the following considerations need to be made prior to extubation¹⁰¹:

- Airway patency—the presence of an air leak of less than 110 mL (cuff leak test) when the endotracheal tube balloon is deflated may identify patients who may be at risk for postextubation upper airway obstruction, for example, prolonged mechanical ventilation, female gender, trauma, and repeated or traumatic intubation.
- Ability to protect airway—patient must be able to expel secretions with an effective cough, lack excessive secretions, or require infrequent airway suctioning (less than every 2 hours).

Extubation failure occurs if there is a need to reinstitute ventilatory support within 24 to 72 hours of a planned extubation. About 4% to 23% of patients who pass a SBT may fail extubation.^{101,103} Nevertheless, a successful SBT coupled with a patent upper airway and ability to protect the airway remains the best predictor of extubation success.

Failure of SBT

If a patient fails the SBT, they are placed back on a comfortable form of ventilatory support and the reason for the SBT failure is determined. Once the reversible causes are corrected and the patient again meets the previously mentioned prerequisites, subsequent SBTs can be performed every 24 hours.^{17,101} In patients who persistently fail, in spite of clinical stability or reversal of their clinical condition, a tracheostomy may be required for prolonged mechanical ventilation during which a gradual ventilatory support reduction strategy is implemented in conjunction with rehabilitative interventions.¹⁰¹

NONINVASIVE POSITIVE PRESSURE VENTILATION

Noninvasive ventilation implies the provision of mechanical ventilatory assistance without the need of an invasive airway. Noninvasive ventilatory techniques can be either negative pressure (eg, tank respirator) or positive pressure ventilation (eg, CPAP and bilevel NIPPV). It is important to distinguish the usage of NIPPV in the setting of acute respiratory failure (hospital setting usually) versus chronic respiratory failure (home setting). The ICU ventilators may combine CPAP with pressure support to provide two separate levels of pressure in the two phases of the breathing cycle. Other modes of ventilation may be utilized to administer NIPPV. These include noninvasive NAVA, proportional pressure ventilation + (PPV+) and average volume assured pressure support. It should be pointed out that PAV does not exist in the noninvasive form commercially.

Advantages of NIPPV

NIPPV avoids complications of invasive ventilation, such as aspiration, trauma, cardiac arrhythmias or hypotension, and volutrauma (early complications) as well as ventilator associated pneumonia, sinusitis,

stress gastritis, airways injury, and problems associated with tracheostomy (late complications). It is more comfortable, requires less sedation, and in the long run proves to be less costly.

Physiological Rationale for Using NIPPV

- Acute exacerbation of COPD: application of NIPPV counterbalances PEEP_i and reduces the WOB.
- Pulmonary edema: NIPPV increases the lung compliance via the application of PEEP or CPAP, thereby preventing alveolar collapse, redistributing intra-alveolar fluid, and improving oxygenation. Additionally, it allows muscle rest by the application of pressure support ventilation.

Indications of NIPPV

It is important to select patients who are likely to benefit from NIPPV. The strong (level A) indications for NIPPV include the following:

1. Acute hypercapnic respiratory failure in the setting of COPD
In a Cochrane systemic review of 14 studies, bilevel NIPPV decreased the risk of intubation [number needed to treat (NNT) = 4] and lowered the mortality (NNT = 10).¹⁰⁴
2. Cardiogenic pulmonary edema
Both CPAP or bilevel NIPPV may be utilized in this setting. A Cochrane systemic review of 32 studies comparing NIPPV plus standard medical care (SMC) with SMC alone demonstrated that the institution of NIPPV (CPAP and bilevel NIPPV) reduced the need for intubation (NNT = 8) and mortality (NNT = 14).¹⁰⁵ Furthermore, there did not appear to be any significant difference between CPAP and bilevel NIPPV with regards to the reduction in intubation or mortality. In addition, there was no increased incidence of acute myocardial infarction either during or after the usage of CPAP or bilevel NIPPV.¹⁰⁵
3. Immunosuppressed patients with pulmonary infiltrates, fever, and acute respiratory failure

In a study of 52 immunosuppressed patients with pulmonary opacities and fever with early hypoxemic respiratory failure, NIPPV delivered by face mask every 3 hours for at least 45 minutes, was administered to 26 patients. An equal number of patients were used as control and given standard treatment without NIPPV. There were fewer patients in the NIPPV group as compared to the standard treatment group who required endotracheal intubation (12 [46%] vs 20 [77%]; $P = 0.03$), fewer who died in the ICU (10 [38%] vs 18 [69%]; $P = 0.02$) and fewer who died in the hospital (13 [50%] vs 21 [81%]; $P = 0.02$). Each of these values was considered significant.¹⁰⁶

A weaker level B indication for the use of NIPPV in acute respiratory failure includes the following conditions:

1. Asthma
2. Extubation failure in COPD patients
3. All other causes of hypoxemic respiratory failure (except cardiogenic pulmonary edema)
4. Postoperative respiratory failure
5. Do not intubate (DNI) patients especially those with COPD and left ventricular failure

Practical Aspects and Institution of NIPPV

Step 1: Indications for use

NIPPV should be considered when dyspnea is at least moderate, that is, respiratory rate more than 24 per minute in the setting of COPD and more than 30 per minute in hypoxemic respiratory failure. Usually there is recruitment of accessory muscle usage. Gas exchange abnormalities generally indicate the development of hypercapnia in COPD exacerbations with falling pH or a drop in the $\text{PaO}_2/\text{FIO}_2$ to less than 300 in the setting of pulmonary edema. In assessing these patients, the likelihood of needing intubation should be approximately 50% or higher.

Step 2: Exclude contraindications to using NIPPV

These include: imminent risk of having respiratory arrest; medical instability (acute shock, upper

gastrointestinal bleeding, etc); agitated or uncooperative patient; profuse secretions which require frequent suctioning; facial trauma; severe hypoxemic respiratory failure with $\text{PaO}_2/\text{FIO}_2$ less than 200; and multisystem organ failure.

Step 3: Selection of appropriate interfaces

It is imperative that appropriate time and resources be utilized to select the mask that is most comfortable to the patient. This should take into consideration patient preferences, nasal or mouth breathing patterns, risk of vomiting, and degree of respiratory failure. In a controlled trial of oronasal versus nasal mask ventilation in the treatment of acute respiratory failure, 35 patients received oronasal masks and a similar number received nasal masks.¹⁰⁷ Sixty-six percent of those receiving oronasal masks were successfully managed versus 49% with the nasal mask although this did not reach statistical significance. However, intolerance to the oronasal mask was 11% versus 34% who were on the nasal mask ($P = 0.02$).

Step 4: Selection of ventilatory modes

Noninvasive ventilatory modes available on critical care ventilators allow for leak compensation, have an adjustable rise time, allow an inspiratory time limit to be set, and have the provision to silence alarms. Usually CPAP with pressure support is instituted to apply pressures to both exhalation and inspiration phases of the breath. However, other modes mentioned previously can also be applied. It is imperative to observe the patient's breathing patterns on these modes rather than just empirically selecting the mode.

Step 5: Settings

Usual practice is to start with low inspiratory positive pressures at about 8 to 10 cm H_2O as well as expiratory positive pressures at about 4 to 5 cm H_2O and readjust relatively soon to achieve adequate V_T of about 5 to 7 mL/kg IBW. More importantly, observing an improvement in respiratory distress with a lowering of the respiratory rate and unloading of accessory muscles must be actively sought. Usually inspiratory positive pressures of up to 20 cm H_2O

and expiratory positive pressures of up to 8 to 10 cm H₂O are utilized. Oxygen is blended to achieve SpO₂ of more than 90% to 92%.

Step 6: Monitoring

Depending upon the clinical acuity, patients may be monitored in an ICU or on a step-down facility. Clinical parameters that are commonly monitored are the level of dyspnea, synchrony with the ventilator, air leaks, mask acceptability, and oxygen saturation. Occasional blood gases are performed within the first 1 to 2 hours after institution of NIPPV. It is also important to stand at the patient's bedside and observe the patient frequently in the first 1 to 2 hours of institution of NIPPV. Those who will fail NIPV will generally do so in the first 2 hours. It is important to ascertain that the patient is breathing synchronously with the ventilator as indicated by the following signs^{108,109}: air leak is minimal (< 24 L/min); desaturation dips less than 3%; and tidal volumes more than 7 mL/kg IBW.

Step 7: When to decide NIPPV is unsuccessful

It is important to assess when NIPPV should be stopped. If there is lack of improvement within 1 to 2 hours, if the patient is intolerant to therapy, if adverse side effects, such as hypotension develop, or if the patient wishes to stop this therapy, NIPPV should be terminated.

SUMMARY

Mechanical ventilation can be life-saving in patients with acute respiratory failure. The goals of mechanical ventilation include providing safe gas exchange; decreasing the WOB; minimizing iatrogenic injury; improving patient-ventilator interactions; and promoting liberation from mechanical ventilation in a timely manner. Technological advancements with complex (microprocessor controlled) modes have made the classification schemas more difficult. None of the new complex modes have been shown to improve morbidity or mortality, although patient-ventilator synchrony is enhanced in some. The choice of the ventilator mode to use and parameters to set may be influenced by the patient's underlying condition, that is, one glove does not fit all. There

is a higher likelihood of permanent discontinuation of mechanical ventilation if a properly timed SBT is utilized to evaluate readiness. The use of NIPPV avoids the complications associated with invasive mechanical ventilation. However, it is important to select the appropriate group of patients who would benefit from its use.

The Acute Respiratory Distress Syndrome

Emily Fish, MD, MPH and Daniel Talmor, MD, MPH

KEY POINTS

- 1 Acute respiratory distress syndrome (ARDS) is characterized by a severe inflammatory process, which causes diffuse alveolar epithelial and capillary damage.
- 2 A number of medical and surgical conditions have been associated with the development of ARDS, with pneumonia and sepsis being the two most common predisposing conditions.
- 3 The Berlin definition of ARDS includes four diagnostic criteria: (1) bilateral opacities on chest radiograph or computed tomography, (2) P_aO_2/F_iO_2 300 mm Hg or less with 5 cm or more H_2O PEEP, (3) respiratory failure not fully explained by cardiogenic edema or volume overload, and (4) 7 days or less from predisposing clinical insult.
- 4 Severity of ARDS is classified by the Berlin definition according to P_aO_2/F_iO_2 : mild (201-300), moderate (101-200), and severe (< 100).
- 5 Management strategies for ARDS are centered on treatment of the underlying clinical disorder while providing supportive care that minimizes ventilator-induced lung injury.
- 6 Current clinical practice guidelines for reducing lung injury include low tidal-volume ventilation, application of PEEP (while maintaining plateau pressures < 30 cm H_2O), and reduction of FiO_2 to lowest necessary value to maintain a goal oxygen saturation of 88% to 95%.
- 7 A number of novel therapies and ventilation strategies are currently under investigation.
- 8 Despite significant advancements in the diagnosis and management of ARDS over the last two decades, mortality estimates remain more than 30% with significant morbidity among survivors.

INTRODUCTION

The acute respiratory distress syndrome (ARDS) was first described in 1967 by Dr David Ashbaugh and colleagues.¹ ARDS is a life-threatening lung condition characterized by acute onset and rapidly progressive dyspnea, tachypnea, and hypoxemia. Several clinical precipitants are associated with the development of ARDS, including sepsis,

pneumonia, aspiration, and transfusion of blood products. Pathogenesis is through a severe inflammatory process, which causes diffuse alveolar damage and alveolar capillary leakage, resulting in a ventilation-perfusion mismatch and poor lung compliance. A significant amount of basic and clinical research has resulted in a greater understanding of ARDS and subsequent improvement in outcomes

through improved ventilatory strategies and supportive care of other organ systems. Morbidity and mortality, however, remain high. This chapter discusses the current understanding of the epidemiology, pathophysiology, management approaches, and prevention of ARDS.

Epidemiology

Accurate estimation of the incidence of ARDS is limited due to variations in diagnostic criteria over the last two decades. In 2005, a prospective cohort study estimated the incidence of acute lung injury (ALI) and ARDS to be approximately 190,600 cases annually in the United States.² Additional cross-sectional studies demonstrated that patients with ARDS represent approximately 5% of hospitalized, mechanically ventilated patients.³ Over the last decade, there has been a decrease in the incidence of hospital-acquired ARDS, which has been attributed to overall improvements in the care of critically ill patients. However, it appears the incidence of community-acquired ARDS is unchanged.⁴

Prior literature has suggested that mortality from ARDS differs by sex and race, with males and African Americans suffering disproportionately lower survival rates.⁵ This sex-related mortality difference may be partially explained by recent data suggesting sex differences exist in patient presentation and likelihood of development of ALI with males more likely than females to develop ALI. The same explanation was not true for race-related differences, as White patients were found more likely than Black patients to develop ALI.⁶

PATHOPHYSIOLOGY

Predisposing Conditions

A number of medical and surgical conditions have been associated with the development of ARDS. Traditionally, these disorders have been categorized into direct (pulmonary) lung injury or indirect (extrapulmonary) lung injury resulting from inflammatory disease states. Direct/pulmonary injuries account for the majority of cases, while pneumonia and sepsis are the two most common causes overall.⁷ Table 19–1 summarizes pulmonary and extrapulmonary predisposing conditions.

TABLE 19–1 Predisposing conditions associated with development of ARDS.

Direct Lung Injury	Indirect Lung Injury
Pneumonia	Sepsis
Aspiration	Acute pancreatitis
Inhalation injury	Burns
Pulmonary contusion	Severe trauma
Near-drowning	Drug or alcohol overdose
Fat embolus	Cardiopulmonary bypass
Amniotic fluid embolus	Transfusion-related lung injury

Mechanism of Injury

ARDS is characterized by a severe inflammatory process, which causes diffuse alveolar epithelial and capillary damage, resulting in three distinct pathologic stages. During the acute exudative stage, increased alveolar capillary permeability leads to alveolar flooding with protein-rich fluid. A release of proinflammatory cytokines coupled with neutrophil extravasation into the alveoli leads to diffuse alveolar injury. Damage to type I and II alveolar cells results in exposition of the underlying basement membrane and impaired surfactant synthesis, respectively. Alveolar collapse ensues and is accompanied by alveolar hemorrhage and hyaline membrane formation. Approximately 7 to 14 days following the initial insult the second fibroproliferative stage begins, represented by varying degrees of neovascularization and fibrosis. From here, most patients enter into a subsequent resolution and repair phase. Few individuals, however, progress to a fibrotic stage resulting in obliteration of the normal lung architecture.⁸

CLINICAL FEATURES AND DIAGNOSIS

Clinical Presentation

The clinical features of ARDS typically manifest within 72 hours of the predisposing event and worsen rapidly. In addition to clinical findings related to the precipitating condition, patients typically present in

FIGURE 19–1 Chest radiograph of ARDS.

respiratory distress with tachypnea, dyspnea, and hypoxemia. Laboratory evaluation reveals hypoxemia with an elevated alveolar-arterial gradient. Supplemental oxygenation is generally inadequate, and endotracheal intubation is often required. Imaging exhibits bilateral alveolar infiltrates on chest radiograph (CXR; [Figure 19–1](#)) and generalized airspace opacities on computed tomography (CT) with predominance in the dependent lung zones ([Figure 19–2](#)).

Diagnosis

In 1994, the American-European Consensus Conference (AECC) defined diagnostic criteria for ALI and ARDS which included four components: appropriate clinical setting, acute severe hypoxemia (defined as a ratio of $P_aO_2/F_iO_2 \leq 200$ mm Hg for ARDS), bilateral infiltrates on CXR, and unelevated pulmonary capillary wedge pressure (PCWP ≤ 18 mm Hg) or no clinical evidence of left atrial hypertension. The AECC used a P_aO_2/F_iO_2 threshold of 200 to differentiate ALI (P_aO_2/F_iO_2 201–300 mm Hg) from ARDS ($P_aO_2/F_iO_2 \leq 200$ mm Hg).⁹

FIGURE 19–2 Chest computed tomography of ARDS.

Due to AECC definition limitations in sensitivity and reproducibility,¹⁰ these criteria were reevaluated and eventually superseded by the Berlin definition of ARDS in 2012. Important modifications to the AECC definition include (1) specification of “acute” as 7 days or less from the predisposing event, (2) elimination of the use of PCWP to rule out cardiogenic edema, and (3) elimination of ALI as a diagnostic category and instead implementing a mild, moderate, and severe grading system.¹¹ [Table 19–2](#) outlines the Berlin definition, which is the current standard for diagnosis.

There is ongoing research into the predictive value of plasma biomarkers for the diagnosis of ARDS. Several ARDS-associated biomarkers have been identified, such as Krebs von den Lungen-6, lactate dehydrogenase, receptor for advanced glycation end products, von Willebrand factor, and interleukin-8.¹² Definitive validation of the use of these biomarkers for

TABLE 19–2 2012 Berlin definition of ARDS.

1. Bilateral opacities on CXR or CT not fully explained by effusion, lung collapse, or nodules
2. P_aO_2/F_iO_2 300 mm Hg or less with 5 cm H_2O or more PEEP
3. Respiratory failure not fully explained by cardiogenic pulmonary edema or volume overload
4. About 7 or less days from predisposing clinical insult, or new/worsening symptoms within prior week
5. Severity classification
 - Mild ARDS: P_aO_2/F_iO_2 201–300
 - Moderate ARDS: P_aO_2/F_iO_2 101–200
 - Severe ARDS: $P_aO_2/F_iO_2 < 100$

Data from ARDS Definition Task Force, Ranieri VM, Rubenfeld GD, et al: Acute respiratory distress syndrome: the Berlin Definition, JAMA 2012 Jun 20;307(23):2526–2533.

diagnosis has not been accomplished, however, and the diagnosis of ARDS remains a clinical one.

MANAGEMENT

Management strategies for ARDS are centered on treatment of the underlying clinical disorder while providing supportive care that minimizes ventilator-induced lung injury (VILI).

Mechanical Ventilation

The majority of patients with ARDS develop respiratory failure severe enough to necessitate mechanical ventilation. While positive-pressure ventilation helps to ensure adequate oxygenation, our understanding of the potential harms of mechanical ventilation has evolved over the last decade. There are four potential mechanisms of alveolar damage in ventilated patients with ARDS: (1) barotrauma caused by excessive airway pressures, (2) volutrauma caused by over distension of alveoli from high tidal-volume ventilation, (3) atelectrauma caused by shearing forces on alveoli from inspiratory opening and expiratory collapse, and (4) biotrauma caused by the release of proinflammatory cytokines from excessive mechanical forces on the lung.¹³

A substantial amount of basic and clinical research has been devoted to understanding optimal ventilator strategies to reduce VILI, which are summarized as follows.

Low Tidal-Volume Ventilation

One strategy for reducing lung injury during mechanical ventilation is the use of low tidal-volume (V_t) ventilation. This became the standard of care following the landmark National Heart, Lung, and Blood Institute's ARDS Network (ARDSNet) trial in 2000, in which a lower V_t (goal 6 mL/kg ideal body weight) with lower plateau-pressure (< 30 cm H_2O) was compared to a higher V_t and plateau-pressure (12 mL/kg ideal body weight and < 50 cm H_2O). Patients randomized to the low V_t /low plateau-pressure group had a reduced 28-day mortality and developed fewer instances of organ failure.¹⁴ These findings have been confirmed by additional work showing increased intensive care unit and hospital mortality in patients ventilated with higher V_t .¹⁵

Positive End-Expiratory Pressure

Another strategy used to reduce injury during mechanical ventilation is the application of positive end-expiratory pressure (PEEP) to reduce cyclical alveolar opening/collapse. However, the optimal level of PEEP in ventilated patients with ARDS remains controversial given the opposing risks of alveolar overdistension and hemodynamic compromise. In a meta-analysis of trials comparing high-PEEP and low-PEEP strategies (14 cm H_2O vs ~ 8 cm H_2O), patients with moderate to severe ARDS ($P_aO_2/F_iO_2 \leq 200$) showed a small but significant improvement in survival among the higher PEEP group. However, this mortality benefit did not exist when all ARDS patients ($P_aO_2/F_iO_2 \leq 300$) were included in the analysis.¹⁶ One possible explanation for these findings is that patients with moderate to severe ARDS (with more significant edema and potentially recruitable lung) may respond favorably to higher PEEP, whereas patients with mild ARDS (and less proportion of recruitable lung) may experience alveolar distension of their healthy, already-aerated lung tissue. At this time, clinical practice guidelines recommend titrating PEEP to maintain an oxygen saturation of 88% to 95% and a plateau pressure of 30 cm H_2O or less to avoid barotrauma.

Fraction of Inspired Oxygen

While the use of high concentrations of inspired oxygen (FiO_2) is commonly necessary, at least temporarily, for patients with severe ARDS, excessive use of high FiO_2 can cause a spectrum of lung injury. Cellular injury appears to be related to increased production of reactive oxygen species, which impair intracellular molecule function and cause cell death.¹⁷ This can lead to damage of the airways and pulmonary parenchyma. Reducing the FiO_2 to the lowest tolerable level is desirable for all critically ill patients and particularly in patients with ARDS who have already sustained some form of lung injury.

Novel Ventilation Strategies

Transpulmonary pressure-guided ventilation—

Transpulmonary pressure-guided ventilation uses an esophageal balloon-catheter to estimate pleural pressure and titrate PEEP to each individual's lung and chest wall mechanics. This approach targets a positive transpulmonary pressure (P_{TP}) to deliver

enough PEEP to prevent repetitive airspace collapse yet avoiding alveolar overdistension. A preliminary single-centered trial showed that optimizing P_{TP} significantly improved oxygenation and lung mechanics compared to a conventional ventilation strategy.¹⁸ Further investigations are being conducted to examine potential survival benefit.

High-frequency oscillation ventilation—High-frequency oscillation ventilation (HFOV) delivers very small tidal volumes at a high frequency (180–1800 per minute) in an effort to maintain a high mean airway pressure. The supporting theory is that sustaining a constant mean airway pressure during inspiration and expiration will prevent end-expiratory collapse. An initial randomized, controlled trial showed an early, transient improvement in oxygenation among patients ventilated with HFOV versus conventional ventilation.¹⁹ However, a subsequent trial showed no significant differences between both groups and was stopped prematurely due to low inclusion.²⁰

Airway pressure release ventilation—Airway pressure release ventilation is a mode of pressure-controlled mechanical ventilation, which applies continuous positive airway pressure for a prolonged time, followed by a release phase to a lower pressure for a shorter period of time. The prolonged high-pressure phase allows for maintenance of adequate lung volume and alveolar recruitment while the shorter low-pressure phase provides the majority of ventilation and carbon dioxide removal.²¹ APRV was developed to provide lung recruitment while minimizing VILI. Several studies have shown APRV to improve clinical outcomes, such as oxygenation, lung recruitment, respiratory mechanics, and sedation requirement. However, thus far it has not been shown to improve mortality as compared to other lung protective ventilation strategies.²²

Supportive Care

Patients with ARDS require diligent supportive care, including judicious use of sedatives, appropriate fluid management, and adequate nutritional support.

Sedation

The use of sedatives and analgesia in patients with ARDS improves ventilator tolerance²³ and decreases

oxygen consumption.²⁴ However, given the significant morbidity associated with excessive sedation, judicious use of agents is recommended. Moreover, improved outcomes have been demonstrated through the application of strategies for frequent sedation liberation and awakening as well as early mobilization.²⁵

Fluid Management

Although the ARDS definition excludes patients with pulmonary edema exclusively due to volume overload or cardiogenic etiologies, an estimated 30% of patients with ARDS have an elevated pulmonary artery occlusion pressure less than 18 mm Hg. Even in patients without elevated filling pressures, a positive fluid balance is associated with poorer outcomes.²⁶ Thus, conservative fluid management for patients with hemodynamic stability and adequate urine output may be beneficial in patients with ARDS.

Nutritional Support

Given the tremendously catabolic state present among patients with ARDS, nutritional support is advantageous. Enteral feedings are preferable if the gastrointestinal tract is acceptable for intake. Theoretically, enteral feeds with increased fat and decreased carbohydrates should result in less carbon dioxide production, thereby decreasing the degree of respiratory acidosis. The ARDSNet EDEN trial showed no difference in physical function, survival, or cognitive performance among patients receiving trophic versus full enteral feedings.²⁷

Novel Therapies

Paralysis

Neuromuscular blocking agents are used to achieve paralysis and decrease ventilator dyssynchrony. Improved patient–ventilator synchrony is thought to reduce VILI by improving control of low tidal-volume ventilation and decreasing the inflammatory response.²⁸ In patients with ARDS, early, short-term paralysis has been shown to improve mortality without a significant increase in development of muscle weakness.²⁹

Prone Positioning

Prone positioning results in improved oxygenation through three primary mechanisms. First,

redistribution of blood flow to healthier lung regions results in a decreased ventilation perfusion mismatch and recruitment of dependent lung units.³⁰ Mechanically, lung tissue relieved of compression from anterior mediastinal and abdominal structures. Lastly, clearance of respiratory secretions is improved with an associated reduction in ventilator-associated pneumonia.³¹ For patients with severe ARDS ($P_aO_2/F_iO_2 \leq 100$ mm Hg), early application of prone positioning has been shown to confer a survival benefit at 28 and 90 days.³²

Extracorporeal Membrane Oxygenation

During extracorporeal membrane oxygenation (ECMO) blood is rerouted outside the body to an external membrane oxygenator, which acts as an artificial lung to facilitate adequate gas exchange. Major risks include bleeding due to anticoagulation (in particular, intracranial hemorrhage) and complications of large bore vascular access. While initial studies showed no improvement in mortality, a more recent trial suggested a potential survival benefit for patients put on ECMO,³³ though other studies have not reproduced this benefit. Currently, ECMO is reserved as an option for rescue therapy for patients with severe ARDS and refractory hypoxemia.

Pulmonary Vasodilator Pharmacotherapy

Inhaled vasodilators, such as nitric oxide (NO) have been used in ARDS to improve oxygenation by selectively dilating pulmonary arterial vasculature and decreasing ventilation/perfusion mismatching. While inhaled NO has been shown to improve oxygenation in some ARDS patients with refractory hypoxemia, it has not shown a reduction in mortality.³⁴ Thus, inhaled NO has not been used routinely and is instead reserved for patients with intractable hypoxemia.

PROGNOSIS AND OUTCOMES

Despite significant advancements in the diagnosis and management of ARDS over the last two decades, recent mortality estimates remain more than 40%.³⁵ Recent studies have suggested an improvement in survival over time; however, this appears to instead reflect a shift in clinical trials to enroll patients with less severe ARDS.³⁷

Among patients who survive ARDS, there is frequently appreciable morbidity that persists years later. Decreased functionality, impaired exercise intolerance, negative psychosocial sequelae, and decreased quality of life have been shown to persist up to 5 years following discharge.³⁸

Venous Thromboembolism

Erica Bang, MD and
Stephen M. Pastores, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Venous thromboembolism (VTE) continues to elude diagnosis due to its diverse presentations and etiologies.
- 2 Proximal deep vein thromboses (DVT) have a 90% likelihood of progressing to pulmonary embolism (PE).
- 3 Although DVT and PE have similar risk factors and many overlapping features, the risk of death within 1 month is far higher in patients with PE than with DVT; thus, aggressive management for PE is recommended compared to isolated DVT.
- 4 Risk stratification based on pretest probability results in a cost-effective and practical diagnostic evaluation of VTE.
- 5 The major complications of anticoagulant therapy for VTE are hemorrhage and heparin-induced thrombocytopenia.
- 6 Focus must lie in the diagnosis, treatment, and prevention in order to improve survival of the critically ill patient with VTE.

INTRODUCTION

Venous thromboembolism (VTE), manifested as either deep venous thrombosis (DVT) or pulmonary embolism (PE), is a leading cause of morbidity and mortality in the critically ill patient. Standardizing for age and race, the incidence of VTE in the United States is approximately 70 to 120 cases per 100,000 individuals. The incidence of VTE increases exponentially as the population ages although no difference is apparent between genders. The high incidence of VTE is mainly dominated by PE diagnosed at autopsy and as a contributory factor in 4% to 11% of deaths. Despite appropriate therapy, 1% to 8% of patients with PE will not survive and others will experience long-term complications including postphlebotic syndrome (40%) and chronic thromboembolic pulmonary hypertension (4%). In the International Cooperative Pulmonary Embolism

Registry, the death rate was 58% in patients who were hemodynamically unstable at the time of presentation and 15% among those who were hemodynamically stable.

VTE often eludes diagnosis due to its wide variety of presentations and diverse pathophysiological mechanisms. The diagnosis of PE is confirmed by objective testing in only about 20% of patients. Accurate diagnosis of VTE can minimize the risk of thromboembolic events and complications related to unnecessary anticoagulation and treatment. Consequently, the Agency for Healthcare Research and Quality ranks prevention of VTE as the first priority out of 79 preventive initiatives that can improve patient safety in healthcare settings.

Because DVT and PE have a spectrum of presentations, they have been approached by many clinicians in an algorithmic manner to address diagnosis,

treatment, and prevention. The clinical presentation of VTE ranges from asymptomatic tachycardia to respiratory failure and hemodynamic instability. Additionally, VTE can occur spontaneously or from predisposing risk factors, catheter related, and may arise from genetic predisposition. In more than half of the cases, VTE is provoked by surgery, immobilization, advanced age, pregnancy, the use of oral contraceptives, or hormone-replacement therapy. The difficulty for clinicians lies in the early recognition and prompt treatment of VTE because of these widely diverse presentations. Prevention of DVT/PE in the ICU patient also poses many difficulties in choosing the appropriate regimen for prevention based on the risk-benefit ratios. The goal is to prevent recurrence because this can be fatal in approximately 5% of patients and prolonged therapy with anticoagulants in itself carries bleeding risks.

RISK FACTORS AND PATHOPHYSIOLOGY

Risk factors for VTE include increased age (≥ 40 years), obesity, prior VTE, malignancy, prolonged immobilization, major surgery, trauma, cardiac failure, pregnancy, hormone replacement therapy, and oral contraceptive therapy. Critically ill patients are especially at high risk for VTE due to severe underlying disease, immobility, and central venous catheterization.

According to Virchow's triad, the pathophysiology of thrombosis lies in three mechanisms: vessel wall injury, stasis, and hypercoagulability. A failure of one of these components leads to clot formation and DVT/PE. Hypercoagulable states may be inherited or acquired. The inherited type should be expected in patients with recurrent or life-threatening VTE, family history of thromboembolism, those younger than 45 years old, no acquired risk factors, and females with multiple miscarriages. Inherited risk factors for VTE include factor V Leiden (activated protein C resistance), protein C and S deficiency, antithrombin III deficiency, prothrombin gene mutation, dysfibrinogenemia, and disorders of plasminogen. Acquired hypercoagulable states include antiphospholipid antibody syndrome (anticardiolipin antibodies, lupus anticoagulant) and hyperhomocysteinemia.

The location of the VTE is another factor in risk evaluation and treatment with anticoagulation. The most common site of DVT is the calf vein but only 15% to 20% will extend proximally into the deep proximal veins. The deep vein thromboses that are of significance are those that occur more proximally, which typically is in the posterior tibial vein and the common femoral vein. Those with proximal vein thromboses have a 90% likelihood of developing PE. Identifying high-risk thrombi in the proximal veins is imperative to prevent the progression to PE; superficial veins thromboses rarely are associated with PE. Hypercoagulable states can also lead to venous thromboses in the superior and inferior vena cava (IVC), renal veins, and hepatic veins.

Upper extremity DVT can occur and involve the brachial, axillary, and subclavian veins and can extend proximally to the brachiocephalic vein, internal jugular vein, or superior vena cava. They account for less than 10% of all DVTs and approximately 75% are provoked by the placement of pacemakers and central venous catheters either in the internal jugular or in subclavian vein. In addition, right atrial thrombi can occur due to venous catheters or cardiac disease, such as atrial fibrillation, cardiomyopathy, ventricular aneurysms, and malignancy. About 5% of patients with arm DVT will have a PE, 20% will have postthrombotic syndrome, and 8% will have recurrence if untreated.

The hypoxemia that is observed in patients with PE is caused by the ventilation-perfusion mismatch resulting from increased physiologic dead space and intrapulmonary shunting. This is commonly associated with increases in minute ventilation and airways resistance, decreased vital and diffusion capacities, and in patients with a potentially patent foramen ovale, progressive pulmonary hypertension may lead to intra-arterial right-to-left shunting and severe refractory hypoxemia. Hemodynamic instability may result from the obstruction of the pulmonary circulation and increase in pulmonary vascular resistance, which impedes right ventricular outflow leading to reduced left ventricular preload and ultimately, a decreased cardiac output. Patients with underlying cardiopulmonary disease are more likely not to tolerate increases in pulmonary artery pressures and thus are more susceptible to developing right heart failure.

CLINICAL PRESENTATION

The clinical presentation of VTE can extend to a wide spectrum of signs and symptoms which present a multitude of diagnostic challenges. Both DVT and PE can present with nonspecific signs and symptoms, such as shortness of breath, fever, tachycardia, pain, and even no symptoms at presentation. However, both can have specific presentations, such as patients with DVT can present with erythema, leg swelling, tenderness, or pain, whereas those with acute PE can present with chest pain, dyspnea, unexplained sustained hypotension, hemoptysis, syncope, increased P_2 on physical exam, right heart failure, respiratory failure, and death. It is important to note that many of the signs and symptoms of PE may frequently be seen in patients with concomitant cardiac and pulmonary disease, and that these manifestations may be a result of a coexisting disease or a superimposed acute PE.

Acute PE can be massive or massive. Massive PE is characterized by hypotension (defined as a systolic blood pressure < 90 mm Hg) or shock and accounts for 5% of all cases of PE. Submassive PE is variably defined on the basis of right ventricular (RV) enlargement, dysfunction, ischemia, or strain on echocardiography, computed tomography (CT), or with cardiac biomarkers (troponins or B-type natriuretic peptide, BNP) with no associated hemodynamic instability.

DIAGNOSTIC WORKUP

The diagnostic workup for VTE should be tailored to the severity of the clinical presentation and depends on whether the patient is hemodynamically stable or hemodynamically unstable. Clinical judgment and clinical prediction rules are useful in establishing a pretest probability of DVT and PE in which patients are typically classified into low-, moderate-, or high-risk categories. These clinical prediction rules should drive the diagnostic workup and facilitates the interpretation of diagnostic tests.

IMAGING STUDIES

Acute DVT

Several imaging modalities are available to detect acute DVT, including venous ultrasonography, impedance plethysmography, computed tomography (CT)

venography, magnetic resonance imaging (MRI), and contrast venography. Venous ultrasonography of the lower extremities is the preferred noninvasive test for the diagnosis of symptomatic proximal DVT. Failure to demonstrate collapsibility or flow indicates a DVT. Venous ultrasonography has a very high sensitivity and specificity of 95% and 98%, respectively. Additionally, both compression and Doppler ultrasonography can be used to diagnose upper extremity DVT.

Impedance plethysmography uses electrical current to estimate venous outflow obstruction when blood flows out of the leg venous system after release of a thigh pressure cuff. Failure to change impedance is presumptive evidence of a proximal DVT. However, other forms of venous obstruction and congestive heart failure can provide false-positive results.

MRI and CT venography can be highly accurate and have the advantage of evaluating both PE and DVT in a single study. However, MRI is expensive, time consuming, and restricted in patients with metallic devices and the additional irradiation associated with CT venography may not be desirable. Contrast venography is invasive and also requires radiocontrast material and should only be considered if noninvasive testing is nondiagnostic or impossible to obtain.

Pulmonary Embolism

Initial evaluation of a patient with suspected PE with nonspecific symptoms should include examination of the electrocardiogram for tachycardia, T-wave and ST-segment changes, and right- or left-axis deviation, arrhythmias, and less commonly for the classic pattern of $S_1Q_3T_3$, right ventricular strain, and new, incomplete right bundle branch block. Chest radiography is usually abnormal in more than 80% of patients with PE and helps to rule out and identify other conditions, such as pneumothorax, rib fracture, pneumonia, and pulmonary edema. Classic radiographic signs suggestive of PE include Westermarck's sign (focal decrease in vascularity or oligemia distal to the pulmonary artery occlusion) and Hampton's hump (wedge-shaped opacity at the costophrenic angle indicating pulmonary infarction).

CT angiography has essentially replaced ventilation/perfusion (V/Q) scan and pulmonary angiography as the diagnostic imaging modality of

choice in patients with suspected PE. In the Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) trial, CT angiography had sensitivity and specificity rates of 83% and 96%, respectively. Limitations of CT angiography include the risk of adverse reactions to contrast (nephrotoxicity or anaphylaxis) and lack of portability.

Ventilation-perfusion scans are generally reserved for patients with renal failure or allergy to contrast dye. A normal V/Q scan essentially rules out PE. However, V/Q scanning is diagnostic in only 30% to 50% of patients with suspected PE. In PIOPED II with the exclusion of patients with intermediate or low probability scans, the sensitivity of a high probability (PE present) scan finding was 77%, whereas the specificity of very low probability or normal (PE absent) scan finding was 98%. Contrast-enhanced magnetic resonance angiography may also be useful in patients with suspected PE in whom radiographic contrast material or ionizing radiation are relatively contraindicated (eg, renal failure and pregnancy).

Echocardiography (transthoracic or transesophageal) is particularly useful in patients suspected of acute PE who may not be stable for transport for CT angiography or V/Q scanning and may also help to guide management. Classic echocardiography signs of PE on echocardiography include dilatation and hypokinesis of the right ventricle, McConnell's sign (free wall RV hypokinesis that spares the apex), paradoxical motion of the interventricular septum, tricuspid regurgitation, and lack of collapse of the IVC during inspiration. Transesophageal echocardiography can confirm the diagnosis of PE by showing emboli in the main pulmonary arteries. Right ventricular dysfunction defined as RV dilation (apical 4-chamber RV diameter divided by LV diameter > 0.9) or RV systolic dysfunction is associated with increased mortality in patients with acute PE. Additionally, among hemodynamically stable patients with PE, the association between an increased troponin level and RV dysfunction on echocardiography identifies a subgroup of patients at particularly high risk for an adverse outcome.

Pulmonary angiography remains the gold standard for diagnosis of PE. However, it is invasive and associated with several complications including renal failure, respiratory failure and bleeding and thus is now rarely utilized for diagnosis of PE.

LABORATORY FINDINGS

D-Dimer

D-dimer is a specific fibrin degradation product that has been widely studied in patients with acute DVT and PE. The rapid enzyme-linked immunosorbent assay is the most commonly used method for measurement of D-dimer. When used in conjunction with a low clinical pretest probability for VTE, D-dimer testing is very sensitive and has a high negative predictive value in excluding the presence of DVT. Several studies have shown that D-dimer testing can decrease the need for further testing such as repeat venous ultrasonography. However, the specificity rates of D-dimer testing are low particularly in patients with cancer, pregnant women, and hospitalized and elderly patients.

Arterial Blood Gas

Arterial blood gases (ABG) have a limited role in diagnosing acute PE. In those with PE associated with hemodynamic instability, the ABG typically shows hypoxemia with an increased alveolar-arterial (A-a) gradient. However, in the PIOPED study, 7% of patients with angiographically documented PE had completely normal ABG measurements. Due to the increase in minute ventilation, patients with PE can demonstrate normal or decreased $p\text{CO}_2$ and respiratory alkalosis.

Cardiac Biomarkers

Elevated levels of serum troponin I or T are noted in 30% to 50% of patients with a moderate or large PE and can indicate RV strain, ischemia, or impending myocardial infarction and are predictive of a poor outcome. One meta-analysis showed that elevated levels of troponin were associated with an increase in the short-term risk of death by a factor of 5.2 (95% confidence interval [CI], 3.3-8.4) and an increase in the risk of death from PE by a factor of 9.4 (95% CI, 4.1-21.5).

BNP (and its precursor, N-terminal pro-BNP) are released in response to increased cardiac filling pressure and are frequently elevated in patients with significant PE. Similar to patients with PE who have elevated troponins, patients with elevated

levels of BNP and pro-BNP have an increased risk of an adverse in-hospital outcome as compared with patients with normal levels.

Algorithms for DVT and PE

Validated algorithms are important to evaluate patients with suspected DVT along with objective testing to confirm the diagnosis. Risk factors for DVT should be identified including malignancy, recent surgery, history of prolonged bed rest or immobilization, obesity, lower extremity trauma, pregnancy, and use of oral contraceptives or hormone replacement therapy. The 2012 American College of Chest Physicians (ACCP) consensus guidelines recommend the following goals for nonpregnant patients with a suspected first DVT of the lower extremity: reduce overall false negatives to 2% or less as defined by symptomatic DVT or PE within 3 to 6 months after a negative test; reduce the risk of fatal PE after testing less than 0.1%, and reduce the risk of fatal hemorrhage due to anticoagulation to less than 0.1%. The guidelines endorse using the Wells score for risk stratification of patients for likelihood of DVT into low-, moderate-, and high-risk categories. The Wells criteria for DVT include risk factors, such as active cancer, bedridden recently more than 3 days or major surgery within 4 weeks, calf swelling more than 3 cm compared to the other leg, collateral superficial veins present, entire leg swollen leg, localized tenderness along the deep venous system, pitting edema greater in the symptomatic leg, previously documented DVT and alternative diagnosis to DVT as likely or more likely. Wells score of 4 or less is consistent with a low (5%) pretest probability for DVT; 4.5 to 6 is consistent with a moderate (17%) pretest probability, and more 6 with a high (53%) pretest probability of DVT (Table 20–1).

TABLE 20–1 Wells criteria and pretest probability of DVT.

Wells Score	Probability of DVT
Low	5%
Moderate	17%
High	53%

In patients with a low pretest probability for DVT in the leg, the guidelines recommend checking either a moderately or highly sensitive D-dimer and compression ultrasound of the proximal leg veins rather than whole leg ultrasound. D-dimer testing is preferred over compression ultrasound of the proximal veins as the initial test. If D-dimer is negative, no further testing is necessary; if D-dimer is positive, compression ultrasound of the proximal leg veins should be performed, and if this is positive, then the patient should be treated without further testing.

In patients with a moderate pretest probability for DVT in the leg, the guidelines recommend checking either a highly sensitive D-dimer (unless the patient has a comorbid condition that would likely elevate the D-dimer level, such as cancer or recent surgery or trauma), compression ultrasound of the proximal leg veins, or whole leg ultrasound. If the highly sensitive D-dimer is negative, then no further testing is needed. If the highly sensitive D-dimer is positive, then compression ultrasound of the proximal leg veins or the whole leg is recommended. A negative ultrasound should lead to a repeat compression ultrasound in 1 week and checking a moderate/high sensitivity D-dimer. If the compression ultrasound is negative, no further testing is warranted. If the D-dimer test is negative, no further testing is needed. If whole leg ultrasound is chosen and is negative, no further testing is also recommended. If compression ultrasound of the proximal leg veins or whole leg ultrasound is positive, the patient should be treated without further testing. If whole leg ultrasound is only positive for isolated distal (calf vein) DVT, serial ultrasounds are recommended to ensure the DVT does not propagate proximally rather than treating with anticoagulation. Approximately 15% to 20% of calf vein thrombi can extend into the proximal veins especially within the first 7 days; thus the need for serial ultrasound examinations.

In patients with a high pretest probability for DVT in the leg, the guidelines recommend either compression ultrasound of proximal leg veins or whole leg ultrasound. If either ultrasound examination is positive, the patient should be treated without further testing. If the whole leg ultrasound is negative for DVT, no further testing is recommended. If the compression ultrasound of the proximal leg veins

is negative, one can either repeat the ultrasound in 1 week and if negative no further testing is recommended, or check a high sensitivity D-dimer and if negative, no further testing is needed. If D-dimer is positive, repeat compression ultrasound in one week is recommended and if negative, no further testing. D-dimer should not be used as a stand-alone test to

rule out DVT in patients with a high pretest probability for DVT.

A diagnostic algorithm (Figure 20–1) with a dichotomized version of the Wells clinical decision rule, D-dimer testing, and CT has been shown to be useful in guiding management decisions in almost 98% of patients with clinically suspected PE.

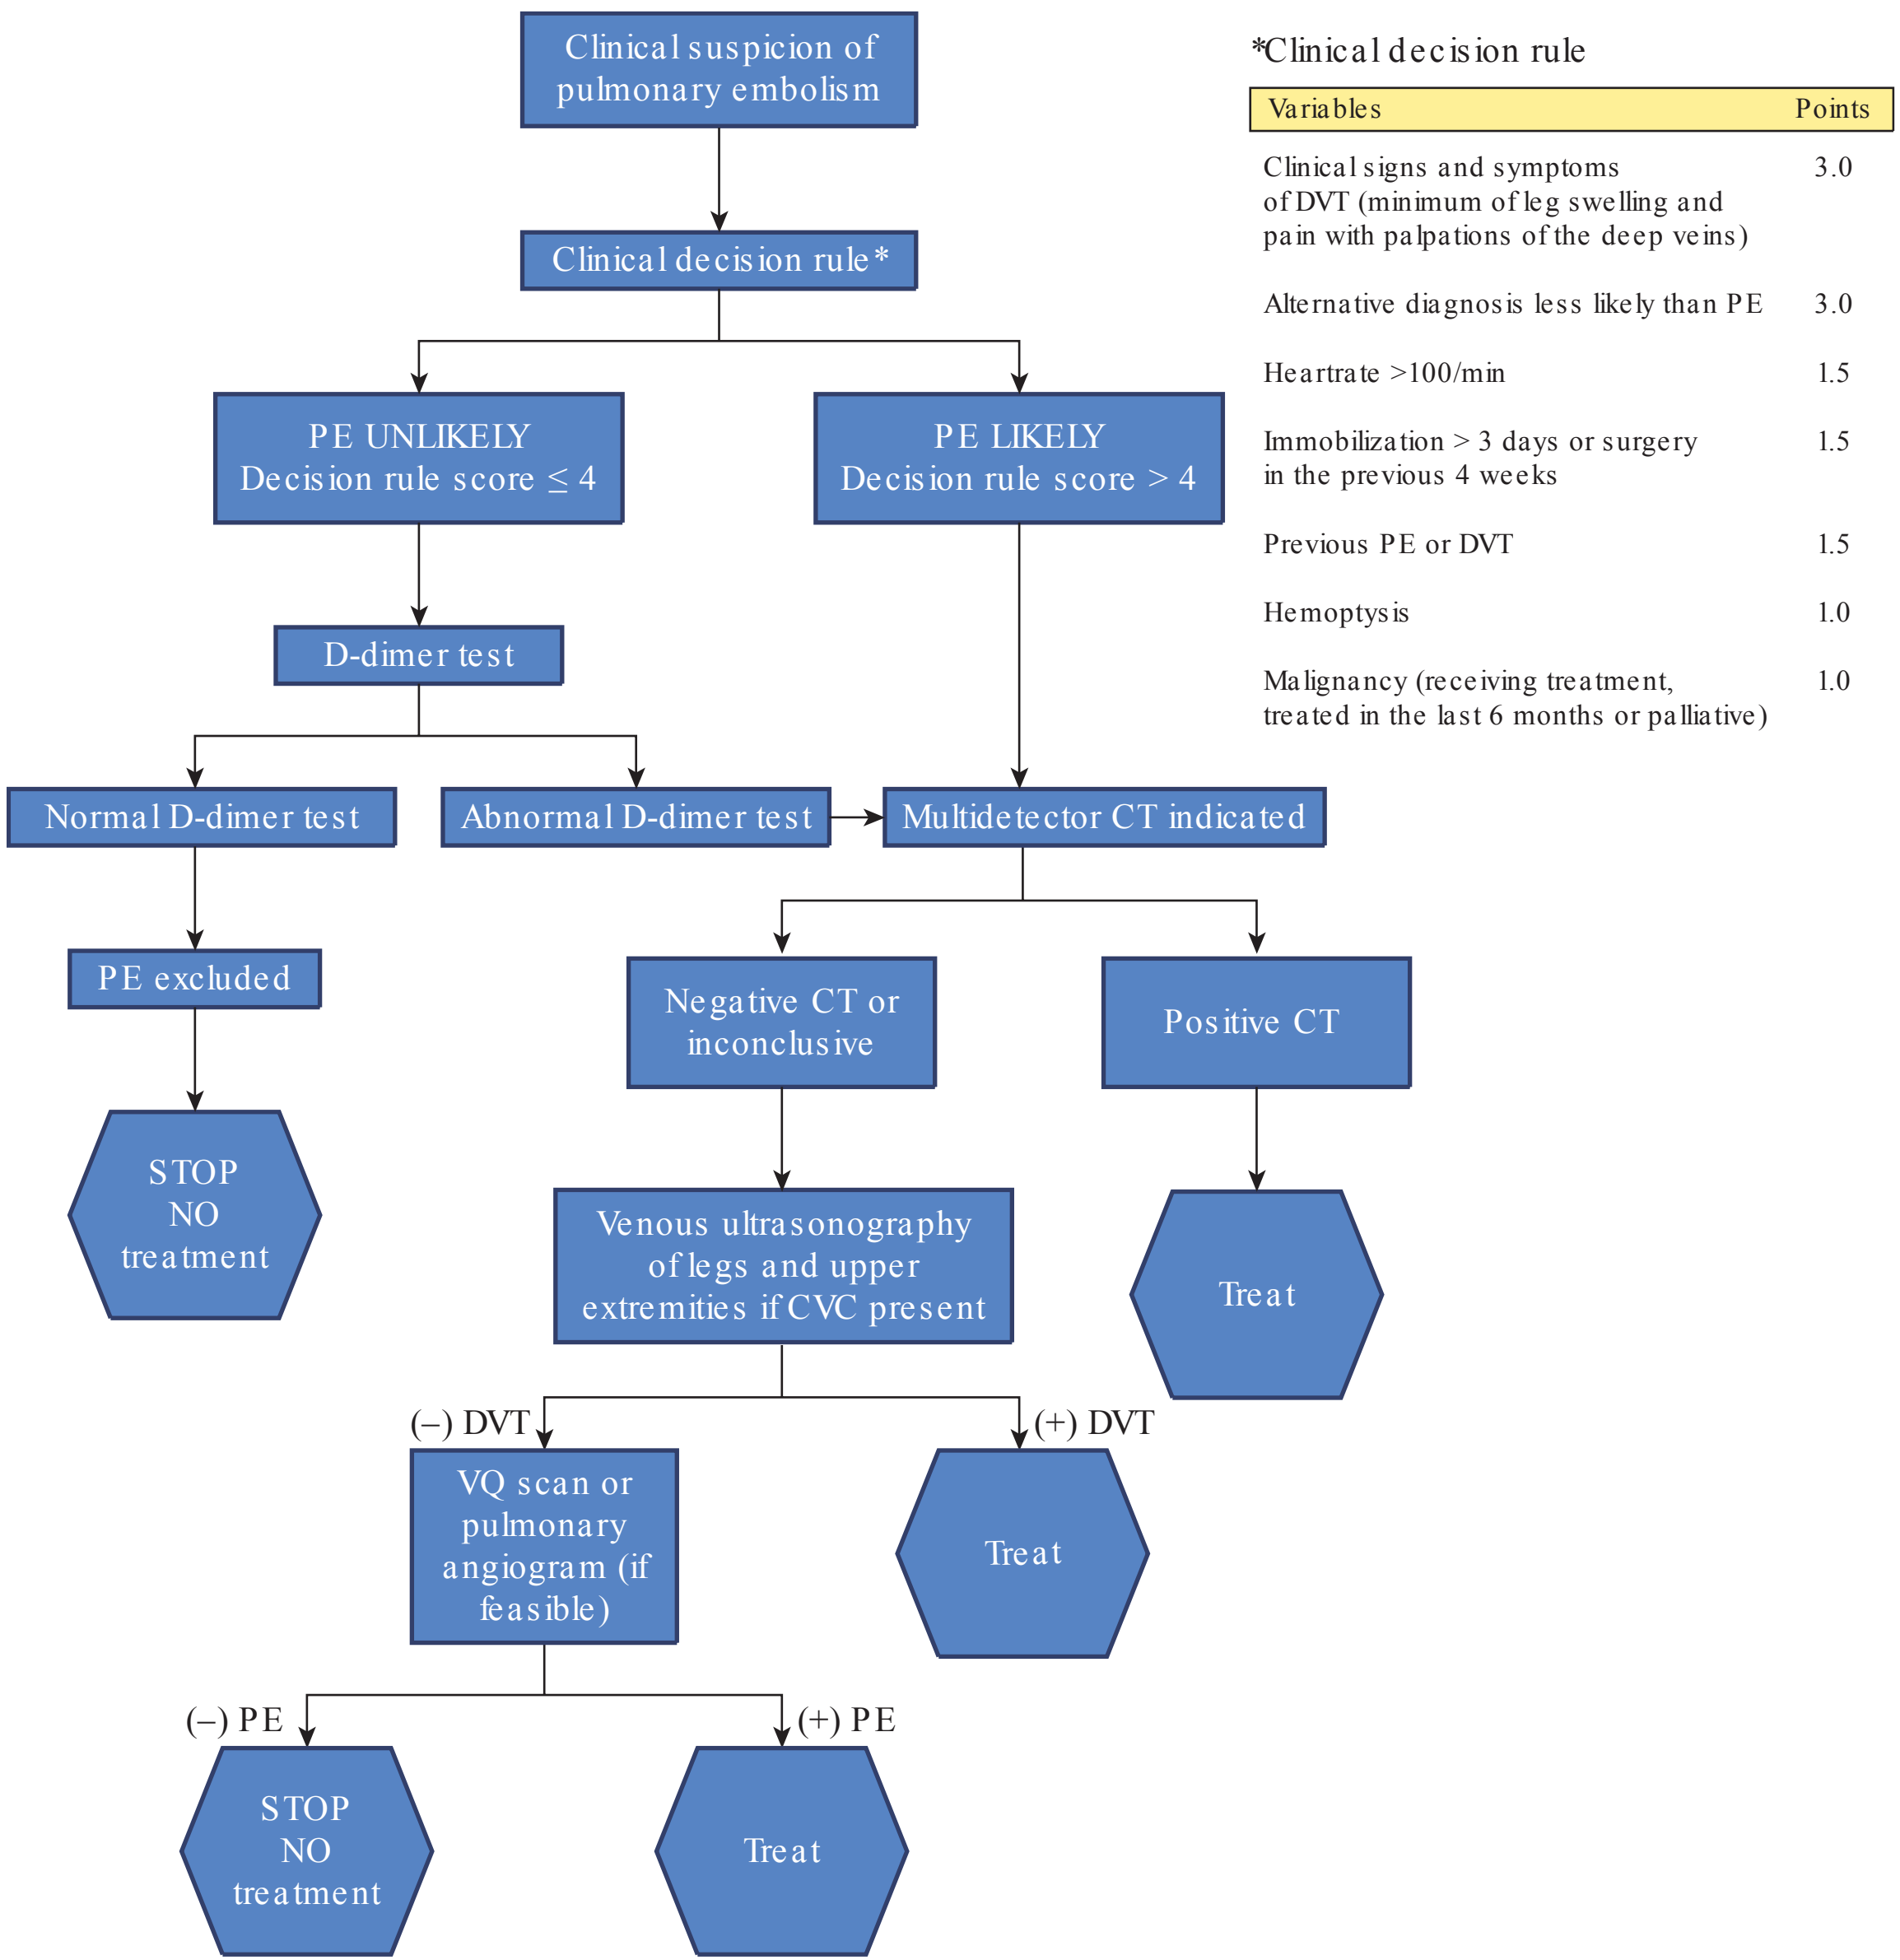

FIGURE 20–1 Diagnostic algorithm in patients with clinically suspected PE (Reproduced with permission from Pastores SM: Management of venous thromboembolism in the intensive care unit, J Crit Care. 2009 Jun;24(2):185-191.)

TREATMENT

Anticoagulation

In patients with a high clinical suspicion of acute DVT, treatment with parenteral anticoagulants is recommended while awaiting the results of diagnostic tests. For those with documented DVT and PE, anticoagulation is the mainstay of treatment if no contraindications exist. The recently released 2016 ACCP guidelines suggest the use of direct oral anticoagulants (DOACs) such as dabigatran, rivaroxaban, apixaban, or edoxaban over vitamin K antagonist (VKA) in patients with DVT of the leg or PE and no cancer. For patients with DVT of the leg or PE and no cancer who are not treated with DOACs, the guidelines suggest the use of VKA therapy over low-molecular weight heparin (LMWH). Initial parenteral anticoagulation with unfractionated heparin or LMWH is given before dabigatran and edoxaban, is not given before rivaroxaban and apixaban, and is overlapped with VKA therapy. In patients with DVT of the leg or PE and cancer, LMWH is favored over VKA therapy and DOACs for the first 3 months. Routine use of compression stockings to prevent postthrombotic syndrome is not recommended in patients with acute DVT or PE who are treated with anticoagulants.

With regards to duration of therapy, at least 3 months of anticoagulation is recommended in patients with a proximal DVT of the leg or PE provoked by surgery or by a nonsurgical transient risk factor. After 3 months of treatment, patients with unprovoked DVT of the leg or PE should be evaluated for the risk-benefit ratio of extended therapy. Extended anticoagulant therapy is recommended in patients with a first VTE that is an unprovoked proximal DVT of the leg or PE and who have a low or moderate bleeding risk.

Administration of IV heparin is usually undertaken using the weight-based heparin dosing nomogram where patients receive a loading bolus dose of 80 units/kg followed by an 18 units/kg/h per hour infusion. The heparin dose is adjusted to maintain an activated partial thromboplastin time of 1.5 to 2.3 times control. IV heparin is favored in LMWH have greater bioavailability when given by SC injection, do not require strict laboratory

monitoring, and have a lower risk of heparin-induced thrombocytopenia (HIT) compared with UFH. Enoxaparin, dalteparin, and tinzaparin are approved for use in the United States. Enoxaparin is typically given at 1 mg/kg SC twice daily or 1.5 mg/kg SC daily, while tinzaparin is given at 175 units/kg SC once daily. Monitoring antifactor Xa levels typically 4 hours after injection may be considered in patients who are morbidly obese, pregnant patients, and patients with renal insufficiency. Fondaparinux is given at a dose of 5 mg SC once daily for patients weighing less than 50 kg, 7.5 mg SC once daily for patients weighing 50 to 100 kg, and 10 mg SC once daily for patients weighing more than 100 kg. Caution should be observed in patients with renal impairment as both LMWH and fondaparinux are retained in these patients.

UFH is suggested for patients with renal impairment (creatinine clearance < 30 mL/min). Warfarin for the treatment of VTE is not ideal in ICU patients given the many drug and food interactions associated with its use and genetic variations in drug metabolism.

Complications of Anticoagulation

The major complications of anticoagulant therapy are hemorrhage and HIT. The frequency of major bleeding was reported at 1.9% and a fatal hemorrhage rate of 0.2% in a large meta-analysis involving over 15,000 patients treated with either UFH or LMWH. HIT is an immune-mediated adverse reaction to heparin that is associated with thrombocytopenia and can lead to venous and arterial thrombosis. Commonly, there is an otherwise unexplained fall in platelet count (absolute thrombocytopenia or > 50% decrease if the platelet nadir remains in the normal range) 5 to 10 days following exposure to heparin. In patients who develop HIT, the heparin should be immediately discontinued and direct thrombin inhibitors such as argatroban or lepirudin should be administered if anticoagulation continues to be required.

In patients receiving UFH or LMWH who develop clinically significant or devastating hemorrhage, protamine sulfate can be administered although the anticoagulant effect of LMWH is only partially reversed. Allergic reactions and bradycardia are side effects of protamine.

Thrombolytic Therapy

The guidelines recommend the use of systemically administered thrombolytic agents (alteplase, streptokinase, and alteplase) in patients with acute PE associated with hypotension (systolic BP < 90 mm Hg) who do not have a high bleeding risk. Thrombolysis may also be considered in selected patients with acute PE not associated with hypotension and with low bleeding risk whose initial clinical presentation or clinical course suggests a high risk of developing hypotension. In the Pulmonary Embolism Thrombolysis (PEITHO) trial published in 2014, the administration of tenecteplase plus heparin was associated a significant reduction in all-cause mortality or hemodynamic decompensation within 7 days, when compared to placebo plus heparin in patients with intermediate-risk PE (acute PE associated with RV dysfunction on echocardiography and myocardial injury as evidenced by a positive troponin I or T test). However, thrombolytic treatment with tenecteplase was associated with a 2% incidence of hemorrhagic stroke. Short-term infusion times (eg, 2-hour infusion of 100 mg of alteplase) through a peripheral vein are suggested over prolonged infusion times and over a pulmonary artery catheter, respectively. Urokinase and streptokinase are given as a loading dose (streptokinase 250,000 units over 30 minutes) followed by continuous infusion of 100,000 units/hour for 24 hours; urokinase 4400 units/kg over 10 minutes followed by a continuous infusion of 4400 units/kg/h for 12 to 24 hours. Heparin infusion is typically continued after thrombolytic therapy. Contraindications to thrombolysis include surgery in the past 10 days, recent puncture or invasion of noncompressible vessels, recent intracerebral hemorrhage or stroke, uncontrolled hypertension, recent trauma, pregnancy, hemorrhagic retinopathy, other sites of potential bleeding, and infective endocarditis. Thrombolytic therapy should be tailored to the complicated ICU patient and risks and benefits heavily weighed prior to administration.

Inferior Vena Cava Filter

The guidelines recommend the use of an IVC filter in patients with acute PE and contraindications to anticoagulation. No randomized clinical trial (RCT) has

evaluated IVC filters as sole therapy in patients with DVT. IVC filters may increase the risk of recurrent DVT and do not reduce the risk of PE or alter mortality. If an IVC filter is indicated in a patient with acute DVT or PE because anticoagulant therapy is temporarily contraindicated (eg, active bleeding), a retrievable filter may be inserted and subsequently removed when it is safe to start anticoagulant therapy. Patients who have an IVC filter inserted should receive a conventional course of anticoagulation (eg, parenteral and long-term anticoagulation) if the contraindication to anticoagulation resolves and should be treated for the same length of time similar to patients who had not had an IVC filter placed. For upper extremity DVT, some institutions can place superior vena cava filters although these are associated with high complication rates than IVC filters; thus, their use should be confined to exceptional circumstances in specialized centers. The risk of recurrent pulmonary emboli after IVC filter placement is 2% to 3%. Complications of IVC filter placement include venous thrombosis at the site of filter insertion, procedural complications, filter malposition and migration, caval occlusion, and sepsis due to device infection. Permanent IVC filters may also predispose to postthrombotic syndrome.

Other Modalities

Surgical pulmonary embolectomy is recommended only in patients with acute PE who have contraindications to thrombolysis, have failed thrombolysis or catheter-assisted embolectomy, or shock that is likely to cause death before thrombolysis can take effect (eg, within hours), provided surgical expertise and resources are available. Mortality from emergency pulmonary embolectomy can be as high as 30% and should be performed only in highly specialized centers.

Other modalities that have investigated include interventional catheterization techniques for massive such as mechanical fragmentation of thrombus with a standard pulmonary artery catheter, clot pulverization with a rotating basket catheter, percutaneous rheolytic thrombectomy, or pigtail rotational catheter embolectomy. Pharmacologic thrombolysis and mechanical interventions are usually combined unless bleeding risk is high.

PREVENTION

Due to the significant morbidity and mortality associated with VTE, prevention is pivotal particularly in high-risk patients, such as those admitted to the ICU. Prevention lies in risk stratification and focusing on identifying preventable or predisposing conditions, such as hypercoagulability and immobility. The Padua Risk Assessment Model (RAM) is the best available validated predictor for DVT/PE risk. Patients scored as low risk (RAM < 4) have a 0.3% risk of developing a DVT and do not require prophylaxis, while those scored as high-risk (RAM score \geq 4) have a 2.2% risk of developing a DVT and require prophylaxis. The guidelines recommend against the use of pharmacologic prophylaxis or mechanical prophylaxis for acutely ill-hospitalized medical patients at low risk of thrombosis. However, the Padua prediction score should not be utilized in critically ill patients who already have an elevated risk for DVT/PE. Patients at moderate or high risk of developing DVT/PE by the Padua prediction score including all critically ill patients who are not bleeding or at high risk for bleeding should receive anticoagulant thromboprophylaxis with either LMWH, UFH, or fondaparinux. Screening for asymptomatic DVT with routine ultrasounds in critically ill patients is not recommended.

Intermittent pneumatic compression devices or graduated compression stockings should be used for patients who are bleeding or at high risk for bleeding. These patients should be switched to anticoagulant prophylaxis as soon as bleeding resolves or once the bleeding risk is considered to be low. Patients considered to be high risk for bleeding and warrant compression devices over anticoagulant prophylaxis include patients with active gastroduodenal ulcer, bleeding in 3 months prior to admission and platelets less than 50,000 mm³.

Shock: Diagnosis and Management

Kevin C. Doerschug MD, MS, FCCP and
Gregory A. Schmidt, MD, FCCP

KEY POINTS

- 1 Shock is acute circulatory failure threatening multiple organ systems and demands prompt diagnosis and urgent resuscitation.
- 2 The main types of shock are hypovolemic, cardiogenic, and distributive shock.
- 3 Shock must be managed rapidly by identifying and treating acute, reversible causes; restoring intravascular volume; infusing vasoactive drugs; using mechanical adjuncts, when applicable; and supporting vital functions until recovery.
- 4 Bedside goal-directed echocardiography should be performed to clarify or confirm the etiology of shock; identify readily treatable contributors (such as tension pneumothorax or cardiac tamponade); and seek clues to fluid responsiveness.
- 5 A comprehensive assessment of the adequacy of perfusion is useful to guide resuscitation, rather than merely aiming for an arbitrary mean arterial pressure.

INTRODUCTION

Shock is acute circulatory failure threatening multiple organ systems and producing a grave threat to survival. Most patients will be hypotensive (mean arterial blood pressure [MAP] < 60 mm Hg) and are often tachycardic, tachypneic, and exhibit overt end-organ dysfunction, such as oliguria, encephalopathy, or lactic acidosis ([Table 21–1](#)). The basis for shock may be readily evident from the presentation, such as following trauma, or when symptoms or signs of hemorrhage, fluid loss, or sepsis are evident. A subset of shock patients will have normal blood pressure (even hypertension is possible); many will also lack tachycardia. In such patients, the diagnosis may be challenging, especially since there is such interindividual variance in normal values for blood pressure. Subtle or atypical presentations of shock

may require a high index of clinical suspicion. Initially, shock is reversible, but rapidly progresses to cellular injury, cell death, failure of critical organ systems, and an irreversible state that terminates in death. Timely resuscitation blunts inflammation and mitochondrial damage, potentially reducing the burden of early and late morbidity. Because delays in

TABLE 21–1 Recognizing shock.

Hypotension
Tachycardia
Tachypnea, respiratory failure, or respiratory alkalosis
Encephalopathy, anxiety, or agitation
Oliguria or AKI
Lactic acidosis
Skin mottling, cool extremities, cyanosis, livedo reticularis
Low mixed venous or central venous oxyhemoglobin saturation values

resuscitation may be lethal, shock demands prompt diagnosis and urgent resuscitation.

DIFFERENTIAL DIAGNOSIS OF SHOCK

Shock is divided into three types: hypovolemic, cardiogenic, or distributive. In a patient with new-onset shock, it is usually possible to categorize the type of shock within minutes based on a concise history and targeted examination. In a patient with shock, a wide pulse pressure accompanied by warm extremities and brisk capillary refill is evidence of high cardiac output (CO; distributive shock). Alternatively, a narrow pulse pressure, cool extremities, and delayed capillary refill suggest low CO. Low CO shock is comprised of hypovolemia and pump failure. In the subset of low output shock, an assessment of intravascular volume can further differentiate hypovolemia from cardiogenic causes of shock. Bed-side goal-directed echocardiography¹ (GDE) should be performed to clarify or confirm the etiology of shock (Table 21–2); identify readily treatable contributors (such as tension pneumothorax or cardiac tamponade); and seek clues to fluid-responsiveness.

Certainly, there may be overlapping causes, as in the patient with septic shock who has both hypovolemic (before resuscitation) and distributive components; or following calcium channel blocker overdose when there may be both cardiogenic and distributive contributors. These more complex cases can generally be recognized by a systematic approach of performing GDE; identifying fluid responsiveness; estimating global perfusion through venous oximetry, lactate clearance, or measures of stroke volume; and repeating these measures until shock remits or a diagnosis is established. For patients already critically ill who progress to new shock, discerning the type may rely on more invasive measurements or diagnostic steps.

TOOLS FOR DIAGNOSIS AND MONITORING OF RESPONSE

Lactic Acid Levels and Clearance

Shock often produces significantly elevated blood levels of lactic acid; sometimes this precedes hypotension and serves as an early indicator.² In a similar vein, successful resuscitation typically produces

TABLE 21–2 Manifestations of the types of shock.

	Hypovolemic	Cardiogenic	Distributive
Symptoms	Overt blood or other fluid loss	Those of acute cardiovascular disease	Those of infection, inflammation, intoxication, or other
Signs	Cool, clammy extremities	Cool, clammy extremities	Warm extremities, bounding or normal pulses
Pulse pressure	Low	Low	Normal or high
Cardiac output or stroke volume	Low	Low	Normal or high
Venous oxyhemoglobin saturation	Low	Low	Normal or high
Lactic acid concentration	High	High	High
Goal-directed echo findings	IVC small, varying with respiration	IVC full; RV, LV, or valve dysfunction; pericardial effusion	Normal or hyperdynamic
Central venous pressure (or pulmonary wedge pressure)	Low	High	Any

rapidly falling values. In a trial of early goal-directed therapy, targeting a lactate clearance of 10% was as good as aiming for normal central venous oxyhemoglobin saturation.³ Moreover, normalization of lactate values is strongly associated with survival.⁴ For patients with low CO shock (hypovolemic or cardiogenic), the genesis of hyperlactatemia is easy to understand: limited oxygen delivery to tissues cripples oxidative metabolism, causing tissues to shift to anaerobic production of ATP, and increases the generation and release of lactic acid. The lactic acidosis of sepsis (and perhaps some other forms of distributive shock) is more complex. In some patients, tissues may be deprived of oxygen, especially before resuscitation or perhaps in the mesenteric circulation, and produce lactic acid anaerobically. Yet many resuscitated septic patients have high CO, total body oxygen delivery, venous saturations, and tissue oxygen saturations,⁵ along with oxidation-reduction ratios that do not support a theory of anaerobic metabolism. These findings cannot exclude oxygen lack, since microvascular dysfunction⁶ and maldistribution of blood flow⁷ may create hidden zones of hypoxia. Nevertheless, other mechanisms are likely, including enhanced aerobic glycolysis through activation of Na⁺/K ATPase, perhaps mediated by catecholamines.⁸ This may be one reason that treatments for shock directed at augmenting oxygen delivery fail to lower lactic acid values or improve outcomes.^{9,10}

Venous Oximetry

Venous oximetry entails measuring the oxyhemoglobin saturation of central or mixed venous blood. Although central and mixed venous values are not identical, they are closely related and usually change in the same direction. Venous oximetry relies on the Fick Principle for oxygen, stating that the difference between arterial and venous oxygen contents is related inversely to the CO as long as oxygen consumption is constant. Because clinicians defend the arterial content value by maintaining minimum values for arterial saturation, low CO tends to be matched by a low venous saturation value. Some support for the importance of venous oximetry derives from the trial of Early Goal-Directed Therapy in which resuscitation based on central venous oximetry during the first 6 hours of septic shock

led to improved survival.¹¹ Similarly, in trauma patients, low venous saturation was a better harbinger of blood loss than conventional hemodynamic parameters.¹² On the other hand, resuscitation of a broad population of critically ill subjects according to mixed venous oxyhemoglobin saturation had no impact on outcome.¹³

Pulmonary Artery Catheter

The pulmonary artery catheter (PAC) has been widely used to assess CO; mixed venous oxygen saturation; and intrapulmonary and intra-cardiac pressures, and provides a wealth of derived information on the systemic and pulmonary circulation. However its use in the ICU, once considered the standard of care for hemodynamic monitoring, has declined in the last decade due to lack of mortality benefit in critically ill patients,¹⁴ and even in congestive heart failure.¹⁵ Newer, less invasive technologies have largely supplanted the PAC for most critical care monitoring and are considered as follows.

Near-Infrared Spectroscopy

The continuous measurement of oxyhemoglobin saturation in thenar capillaries by near-infrared spectroscopy (NIRS) has the promise of directly monitoring the microvasculature. This technique has provided an early warning of shock progression during acute hemorrhage following trauma.¹⁶ Moreover, the microvascular dysfunction of septic shock is related to organ failures,⁶ while increased microcirculatory flow during resuscitation is associated with reduced subsequent organ dysfunction.¹⁷ Static NIRS measures generally normalize, however, presumably due to shunting and cellular dysoxia, and so may be less useful during prolonged shock states.

Stroke Volume Estimation

Stroke volume can be estimated through a variety of techniques, such as arterial pulse contour analysis, bioreactance, bioimpedance, CO₂ rebreathing, and pulse-wave Doppler analysis of the left ventricular outflow tract. These methods all demonstrate reasonable correlations with invasive measures of stroke volume, with the advantage of minimally or noninvasive technology. None has been shown to improve outcomes in patients with shock so their

potential value remains inconclusive. Further, since large studies of hemodynamic optimization using the PAC failed to demonstrate improved outcomes, it seems unlikely that gathering similar information noninvasively will produce major advances in care.

Goal-Directed Echocardiography

Bedside GDE is now commonplace for the assessment of shock in the ICU, emergency department, and on rapid-response teams. Typically, an intensivist acquires four standard chest views to evaluate ventricular size and function, along with a subcostal view of the inferior vena cava. It allows for rapid assessment, often serially in a patient with rapidly changing conditions, and can prove to be crucial in cases of unsuspected ventricular dysfunction, hypovolemia, cardiac tamponade, or severe acute valve failure. The subcostal view is especially helpful in assessing the inferior vena cava, showing significant cyclic variation with respiration in hypovolemic states, as discussed as follows.¹⁸

MANAGEMENT OF SHOCK

Shock is managed (1) at an urgent tempo; and by (2) identifying and treating acute, reversible causes; (3) restoring intravascular volume; (4) infusing vasoactive drugs; (5) using mechanical adjuncts, when applicable; and (6) supporting vital functions until recovery.

Tempo of Management

Minutes matter when recognizing and resuscitating shock. This principle is emphasized in speaking of the “golden hour” in which the circulation and tissue perfusion are restored before progressive tissue injury and organ failures that rapidly become refractory to subsequent attempts at resuscitation. This golden hour is a time-honored tenet in trauma, and more recently recognized to be also pertinent in septic shock. The initial Early Goal Directed Therapy (EGDT) trial demonstrated that rapid resuscitation to endpoints of central venous pressure, mean arterial pressure, and central venous oxyhemoglobin saturation within 6 hours of presentation improved outcomes compared to a less-aggressive resuscitation.¹¹ Three subsequent trials of

septic shock did not confirm the utility of the original EGDT protocol.¹⁹⁻²¹ However, the mortality rates reported in these later trials, performed in an era when aggressive early resuscitation was the norm, were significantly lower than in previous reports. One interpretation of these results is that, while the appropriate endpoints of resuscitation remain unclear, an environment that favors early, aggressive resuscitation improves outcomes in septic shock.

The appropriate endpoints of shock resuscitation remain elusive. Importantly, resuscitation to an arbitrarily set MAP of at least 65 mm Hg is not sufficient and possibly not necessary. As an example, treatment with a nitric oxide synthase inhibitor leads to increased blood pressures and lower catecholamine use, but also increased mortality.²² These seemingly contradictory effects of therapy may be explained by discrepancies between systemic hemodynamics and the microcirculation; lack of validity of the targets of macrovascular resuscitation (perhaps MAP is less important than believed); or to unrecognized adverse effects of the drug. Several studies have compared specific blood pressure targets finding that achieving a MAP of higher than 65 mm Hg (such as 75 or 85 mm Hg) does not improve outcomes. Targeting microvascular resuscitation is attractive in theory, but real-time assessments of microvascular function are not readily available for clinical use, and effective methods to safely and reliably increase microvascular function have not been found. We advocate a comprehensive assessment of the adequacy of perfusion to guide resuscitation, rather than merely aiming for an arbitrary mean arterial pressure. Serial assessments are likely to be valuable since shock and its resuscitation can produce dramatic changes within hours.

Identify and Treat Reversible Causes

Several causes of shock require specific identification and treatment because general supportive measures will surely fail. Good examples include tension pneumothorax, cardiac tamponade, and ruptured abdominal aortic aneurysm ([Table 21-3](#)). These can be subtle at times, requiring a careful, systematic approach to shock. Intensivist-conducted ultrasound has changed fundamentally the initial examination of the shock patient. Its ability to quickly signal cardiac dysfunction, pericardial

TABLE 21–3 Differential diagnosis of shock.

Hypovolemic shock Intravascular hypovolemia Hemorrhagic shock (GI, trauma, aortic rupture, etc) Renal loss (diuresis, osmotic loss, diabetes insipidus) Gastrointestinal loss (diarrhea, vomiting) “Third space” loss (pancreatitis, postsurgical, sepsis, anaphylaxis, trauma, toxin, idiopathic systemic capillary leak syndrome) Venodilation Anaphylaxis Neurogenic shock Drugs (sedatives, analgesics, nitrates, Ca-channel blockers) Impaired cardiac filling Cardiac tamponade High pleural pressure (PEEP, autoPEEP, tension pneumothorax, massive effusion, abdominal compartment syndrome) Other obstruction to cardiac filling (tumor, thrombus)
Cardiogenic shock Arrhythmia (fast or slow) Systolic LV or RV dysfunction Ischemia Cardiomyopathy Metabolic derangement Drugs (Ca-channel blockers, beta-blockers, other) Sepsis Myocardial contusion Toxins Diastolic dysfunction Ischemia Hypertrophy Restrictive cardiomyopathy Tamponade (as above) Excessive afterload Pulmonary embolism Aortic stenosis; hypertrophic obstructive cardiomyopathy ARDS and its treatment (elevated alveolar pressure) Malignant hypertension Valve dysfunction Aortic insufficiency Papillary muscle rupture Endocarditis Mitral stenosis Device malfunction (ECMO, VAD, IABP)
Distributive (high cardiac output) shock Sepsis Hepatic failure (acute and chronic) Adrenal insufficiency Thiamine deficiency Toxins (salicylate, cyanide, carbon monoxide) Thyroid storm Arteriovenous shunts Cellular dysoxia (prolonged shock states)

effusion, hypovolemia, deep vein thrombosis, pulmonary embolism-in-transit, pneumothorax, aortic rupture, free peritoneal blood, traumatic injuries, sources of sepsis, and other crucial findings makes

ultrasound an essential skill for early diagnosis.²³ Moreover, the intensivist can repeat the ultrasound examination at will to judge the response to interventions or identify complications.

The timing of antibiotics in confirmed or suspected septic shock deserves specific mention in relation to the tempo of shock resuscitation. Appropriate antibiotics must be given within the first hour following the recognition of septic shock. Antibiotic therapy is frequently delayed and often ineffective for the final microbiologic diagnosis. Orders may be delayed due to diagnostic confusion and caregiver attention toward invasive procedures and hemodynamic resuscitation. Systems issues between ordering and administering antibiotics also contribute to these delays. Regardless of cause, delays in appropriate antibiotic administration worsen mortality by approximately 8% per hour of delay.²⁴ For these reasons, broad-spectrum antibiotics should be ordered and administered promptly after a diagnosis of shock when sepsis is in the differential, preferably guided by preplanned order sets. Antibiotics should then be tailored to microbial susceptibilities, as these data are available, or discontinued promptly if an alternative etiology of shock is identified.

Restoring Intravascular Volume

Rapid restoration of intravascular volume is an essential principle of shock resuscitation since fluids may promptly restore perfusion and prevent organ failures. Fluids should be infused at a rapid pace (usually much faster than typical ICU infusion pumps will allow), and in sufficient volume (which can be many liters). This practice allows for periodic reevaluation for clinical response: slower infusions of small volumes may confound the perception of response. Although colloid-containing fluids have some theoretical advantages over crystalloids, clinical trials generally show equivalence. Some colloids, especially synthetic starches, are clearly detrimental and should not be used.²⁵ Because crystalloids are more widely available, cheaper, and at least as effective, they are preferred for shock resuscitation. Although vasomotor function and vasopressors are both less active in acidemic environments, attempts to correct a metabolic acidosis with bicarbonate infusions do not speed resuscitation nor reduce vasopressor requirements, and may lead to worsening intracellular acidosis. Accordingly, bicarbonate infusions should be avoided.

In the setting of acute traumatic shock, questions have been raised about the targets of early fluid resuscitation. Potential downsides of restoring blood pressure to normal before surgical exploration include dilution of clotting factors, hypothermia, and an increased rate of hemorrhage as arterial pressure rises. Several studies suggest that delayed fluid resuscitation for victims of penetrating trauma (aiming for a systolic blood pressure of 70 mm Hg) might improve outcomes.²⁶ Concerns about the risks of persisting hypotension and doubts about whether these data can be generalized to the broad group of patients with traumatic shock have limited its appeal.

While the importance of urgent fluid resuscitation is undeniable, many patients with shock fail to respond, especially following initial resuscitation when shock is due to sepsis.²⁷ Indiscriminant fluid may produce harm by causing pulmonary edema or other organ failures so, especially in the sickest patients with lung and renal failure, an effort should be made to predict fluid responsiveness. In this regard, static measures of the central venous and pulmonary artery occlusion pressures have been shown invalid²⁸ and have been supplanted by dynamic indicators. High-volume positive-pressure ventilation produces pleural pressure changes that affect stroke volume in a cyclical fashion (largely by varying right atrial filling), giving rise to larger fluctuations in stroke volume; vascular flow; and vena caval diameter in preload-dependent individuals. A 13% variation in pulse pressure with breathing is highly sensitive and specific for predicting fluid responders.²⁹ Similarly, useful cutoff values have been determined for variations in vena caval diameter (superior and inferior); aortic and brachial artery flow velocity; left ventricular outflow tract velocity-time integral; and cardiac volumes derived from bioimpedance and bioreactance. Prerequisites for validity include tidal volume of 8 to 12 mL/kg; a fully passive patient; regular cardiac rhythm; and the absence of acute cor pulmonale. Since this tidal volume is larger than generally appropriate, the ventilator should be adjusted before the measurement of variation in order to produce the conditions for validity but then returned to lung-protective volumes. Passive leg raising is a reliable indicator of fluid-responsiveness irrespective of ventilation

mode and cardiac rhythm,³⁰ but is not reliable when there is severe intra-abdominal hypertension. By returning blood held in the capacitance veins to the circulation and thereby raising stroke volume in patients who are on the ascending limb of the Starling curve, it avoids potentially harmful fluid boluses in patients who will not benefit. This method is particularly useful for patients who cannot easily be made passive on the ventilator.

Infusing Vasoactive Drugs

In addition to careful assessment and restoration of circulatory volume, many patients in shock require vasoactive infusions. Norepinephrine is the preferred initial agent given its potency, relatively low propensity to induce arrhythmias, and association with improved mortality compared to dopamine.³¹ To avoid injury caused by accidental infiltration of vasoconstrictors into peripheral tissues, norepinephrine and other vasopressors should be infused through central venous or intraosseous catheters. However, in keeping with the urgent tempo of shock resuscitation, vasoactive infusions into severely ill patients should not be delayed merely because central access is not yet available. Similarly, vasopressors should not be initiated without attempts to restore circulating volume, yet severely ill patients should be resuscitated simultaneously with vasopressors and fluids, with titration of the vasopressors as circulating volume is restored.

The initiation of vasoactive infusions may also provide additional important clues to the underlying physiology. For example, norepinephrine consistently increases blood pressure. However, a concomitant increase in lactic acidosis and fall in venous oxyhemoglobin should prompt reevaluation for inadequate fluid loading or for cardiogenic shock.

When cardiogenic shock is identified or suspected, inotropic agents, such as dobutamine are useful. Like norepinephrine, careful examination during dobutamine initiation may identify additional physiologic perturbations. A rise in arterial pressure (or decrease in norepinephrine requirements) after initiating inotropic agents supports cardiogenic shock physiology. Because dobutamine also causes some arteriolar dilation, if arterial pressure falls with dobutamine one may suspect inadequate

preload or, alternatively, a severely dysfunctional myocardium.

Mechanical Adjuncts for Circulatory Support

When ventricular dysfunction is so extensive that it is refractory to vasoactive infusions (or when valvular incompetence contributes to cardiogenic shock), mechanical adjuncts to aid circulation may be employed. Ideally, these devices are employed as a bridge to definitive correction of the cardiac dysfunction. Intra-aortic balloon counterpulsation has been used extensively in this fashion for decades, although more recent evidence shows that it does not improve outcomes in patients with acute myocardial infarction or cardiogenic shock.^{32,33} Venous-arterial extracorporeal membrane oxygenation (ECMO) also provides circulatory support and can be employed rapidly, even during cardiopulmonary resuscitation. The practice of E-CPR (initiation of ECMO within 15 minutes of cardiac arrest) may lead to improved patient outcomes. Ventricular assist devices (VADs) also provide circulatory support: while slower to employ than ECMO, VADs may be more appropriate for medium- and even long-term support.

General Supportive Care

Patients in shock often have deranged cerebral perfusion and metabolic encephalopathy that would benefit from endotracheal intubation and mechanical ventilation. In severe shock states, lactic acidosis leads to increased respiratory effort, which subsequently increases lactate production, diverts blood flow to respiratory muscles, and draws CO from other vital organs. Mechanical ventilation (either invasive or noninvasive) may decrease oxygen consumption and increase vital organ blood flow and should be considered even in the absence of encephalopathy.

Because shock is usually characterized by inadequate oxygen delivery, increasing arterial oxygen content through transfused red blood cells may be helpful, particularly when shock results from massive hemorrhage. However, this theoretical benefit of transfusions must be balanced with its negative effects, including circulatory overload, inflammatory

effects, and immune suppression as well as recognition that transfused red cells may exhibit impaired oxygen carrying capacity. Studies in patients with acute gastrointestinal hemorrhage and in those with septic shock show that liberal transfusion strategies (to keep the [Hgb] > 9 g/dL) are no better and may be inferior to restrictive targets ([Hgb] > 7 g/dL).^{34,35} While there may be some patients in whom higher targets for hemoglobin may be appropriate (eg, acute coronary syndrome, low central venous oxyhemoglobin saturation despite resuscitation, and other overt manifestation of anemia), we recommend that transfusion be avoided in most patients with shock until the hemoglobin falls lower than 7 g/dL. It is even possible that lower targets could be beneficial for some patients, but these have not been tested.

Critically ill patients with shock have historically been considered fragile, leading to orders for strict bed rest and minimization of physical interventions. More recently, early physical and occupational therapy has been shown safe for critically ill patients and effective in preserving functional independence.³⁶ Many of the subjects in this and similar studies have been in shock, on vasoactive infusions, suggesting that shock is not a contraindication to mobilization. Some patients experience a decrease in vasoactive infusion requirements following mobility sessions suggesting a previously unrecognized, but important intervention for the management of shock.

CPR and ACLS Updates

Carla Venegas-Borsellino, MD and
Maneesha D. Bangar, MD

KEY POINTS

- 1 In- and out-of-the-hospital cardiac arrest remains a substantial public health problem and a leading cause of death in many parts of the world. There is a dramatic variation in the survival rates across various systems of care.
- 2 Major changes were made in the 2010 American Heart Association (AHA) guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care. We will review the studies behind these recommendations.
- 3 Identifying the most accurate and relevant post-cardiac arrest outcomes to measure is a major challenge. The most used measurements are survival to hospital discharge, or neurologically intact survival to discharge.
- 4 Five main components of high-performance CPR have been identified: chest compression fraction, chest compression rate, chest compression depth, chest recoil, and ventilation. Minimizing the interval between stopping chest compressions and delivering a shock improves the chances of shock success and patient survival.
- 4 The 2010 AHA guidelines recommend education to improve the effectiveness of resuscitation. Recommended educational tools include high-quality medical simulators, videos, and written tests accompanied with a performance assessment.

INTRODUCTION

Cardiac arrest is the abrupt cessation of cardiac pump function which leads to death, but in some cases can be reversible by a prompt intervention in the form of cardiopulmonary resuscitation (CPR).¹ In- and out-of-the-hospital cardiac arrest remains a substantial public health problem and a leading cause of death in many parts of the world.² In the United States and Canada, approximately 350,000 people/year suffer a cardiac arrest (approximately half of them in-hospital) and receive attempted resuscitation; approximately 25% of these present with pulseless ventricular arrhythmias.^{3,4} Cardiac-arrest victims

who present with ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) have a substantially better outcome compared with those who present with asystole or pulseless electrical activity (PEA).⁴ Emergency systems that can immediately and effectively implement life support measurement can achieve witnessed VF cardiac arrest survival of almost 50%.⁵ However, there is a dramatic variation in the survival rates across various systems of care, with the most successful systems reporting survival rates five times higher than the least successful.³

The survival rate and the quality of life (specially measured as a neurological performance)

after a cardiac arrest have also changed over time; for example, the US survival rates for hospitalized patients with cardiac arrest improved from 30.4% in 2001 to 42.2% in 2009 as per the US National In-Patient Sample, a national hospital discharge database.⁶ It is important to understand that CPR outcomes are significantly influenced by the underlying pathology and the initial cardiac rhythm at the time of the cardiac arrest. In a nutshell, survival is best for patients with VT or VF.

It is an integrated and coordinated system, starting from initial responders (including both medical professionals and bystanders) to in-hospital caregivers, functioning as a comprehensive whole that will produce the highest likelihood of achieving the desired survival to discharge from hospital outcome. However, research has shown that several factors prevent bystanders from taking action; including fear that they will perform CPR incorrectly, fear of legal liability, and fear of infection from performing mouth-to-mouth.⁷ But a hospital setting does not have these inhibitory factors; hence, hospital personnel have tools in the form of the knowledge about CPR guidelines and resources to fight against cardiac arrest.

Resuscitation is one of the most widely studied topics in medicine. It has been known and practiced since 1740 when performance of mouth-to-mouth resuscitation for drowning victims was recommended by the Paris Academy of Science.⁸ As of December 2013, there were close to 19,000 related references cited in PubMed, with new changes being recommended every few years in how CPR should be administered; so it is important to keep ourselves updated with the latest knowledge and practice of the art of CPR. The American Heart Association (AHA), in cooperation with the International Liaison Committee on Resuscitation, leads the research and management guidelines for CPR. The latest guidelines available for CPR were established in 2010⁷ after an extensive evidence evaluation process that included 356 resuscitation experts from 29 countries who reviewed and analyzed the available literature during the 36-month period before the 2010 Consensus Conference. The experts produced 411 scientific evidence reviews on 277 topics in resuscitation and emergency cardiovascular care. The purpose of this chapter is to review the fundamentals of these

recommendations, to emphasize the new changes made in 2010, and review the evidence-base literature that support these guidelines.

HISTORY OF CPR

Upon review of the history of CPR, the earliest recorded reference to artificial breathing is in the Old Testament, in the book of Kings, where the prophet Elisha restored the life of a boy through a technique that included placing his mouth on the mouth of the child.⁸ Around the 1700s, there was a large number of drowning deaths in the Rhine river near Paris, and even though there were case reports and references to mouth to mouth resuscitation for many years before this, it was not until the 1740s that the technique became well known after the Paris Academy of Science's official recommendation of mouth-to-mouth resuscitation for drowning victims.⁸ In 1891, Dr Friedrich Maass performed the first equivocally documented chest compression on a human.⁸ This resuscitation technique was rediscovered in the 1940s during the polio epidemic in Minneapolis by the anesthesiologist James Elam.⁹

The three most important contributors to modern CPR are Doctors Zoll, Safar, and Kouwenhoven.¹⁰ Safar in the 1950s investigated techniques for airway management and showed that the optimal position for CPR was with the patients' neck extended, mandible supported, in order to insert the oropharyngeal tube to deliver oxygen; Zoll performed and recorded the first successful closed chest human defibrillation in a man with syncope and VF; and Kouwenhoven in 1950s to 1960s developed a closed chest cardiac massage and external defibrillation. Later in the 1960s, Safar et al¹¹ published a paper showing circulatory efficacy of closed-chest cardiac massage and postulated that rhythmic sternal pressure must be accompanied by intermittent positive-pressure ventilation.

In 1960, Dr Kouwenhoven, in association with Drs Knickerbocker and Jude, documented 14 patients who survived cardiac arrest with the application of closed chest cardiac massage¹²; that same year, at the meeting of the Maryland Medical Society in Ocean City, the combination of chest compressions and rescue breathing was introduced.¹³ Two years later, in 1962, direct-current, monophasic waveform

defibrillation was described, and in 1966, the AHA developed the first CPR guidelines, which have been followed by periodic updates.¹⁴ Since then, the AHA has maintained a program to acquaint physicians with closed chest cardiac resuscitation; this program is the forerunner of CPR training for the general public.

In 1979, the concept of Advanced Cardiovascular Life Support (ACLS) was introduced during the Third National Conference on CPR, and in the 1990s, Early Public Access Defibrillation programs were developed with goal in mind of providing training, resources, and the ability of the general public to become proactive and integral in the successful resuscitation of sudden cardiac arrest victims.¹⁵ It was not until 2005 that the International Consensus on Emergency Cardiovascular Care (ECC) and CPR Science with Treatment Recommendations (CoSTR) Conference produced the 2005 AHA guidelines for CPR and ECC.⁷

Two studies published just before the 2005 International Consensus Conference documented the poor quality of CPR performed in both out-of-hospital and in-hospital resuscitations;^{16,17} addressing this, changes in the compression-ventilation ratio and in the defibrillation sequence (from 3 stacked shocks to 1 shock followed by immediate CPR) were recommended to minimize interruptions in chest compressions.⁷ Since 2005, as mentioned earlier, it is more clear that after CPR with early, noninterrupted chest compressions and early defibrillation and ACLS, the best survival chance is for patients with VT or VF. To follow, we will review the major changes from 2010 AHA guidelines for CPR and ECC,⁷ and some of the studies behind these recommendations.

NEW RECOMMENDATIONS FROM 2010 AHA GUIDELINES FOR BASIC LIFE SUPPORT

Traditionally, basic life support (BLS) has three components: achieving a patent airway, delivering lung inflations via mouth to mouth or bag-mask to mouth, and promoting circulation with chest compressions. Studies have demonstrated improved outcomes after out-of-hospital cardiac arrest (OHCA), particularly from shockable rhythms when there

are minimal interruptions in compressions without excessive ventilation.^{5,18,19} In order to prevent wasting time on potentially improper airway maneuvers, the most recent AHA guidelines recommend a significant change in BLS sequence.

CHANGE IN BLS SEQUENCE OF STEPS FOR TRAINED RESCUER FROM A-B-C TO C-A-B

Reasoning: High-quality CPR is the cornerstone of a system of care that can optimize outcomes beyond return of spontaneous circulation (ROSC), where return to a prior quality of life and functional state of health is the ultimate goal. The newest development in the 2010 AHA Guidelines for CPR and ECC is a change in the BLS sequence of steps from “A-B-C” (Airway, Breathing, Chest compressions) to “C-A-B” (Chest compressions, Airway, Breathing) for adult patients. As explained in the AHA guidelines, the A-B-C sequence could be reason why fewer people in cardiac arrest received bystander CPR. A-B-C starts with the most difficult and time consuming set of tasks: positioning the patient’s head correctly, opening the airway, achieving a mouth to mouth seal, and delivering rescue breaths. Also there may be hesitancy on part of a rescuer’s willingness to provide mouth-to-mouth resuscitation. By changing to C-A-B sequence, chest compressions will be initiated sooner and ventilation only minimally delayed until the first cycle of chest compressions is completed. The only exception to this sequence is in drowning victims and newborn patients where conventional CPR must be done.

In a prospective, population-based, observational study involving patients with emergency responder resuscitation attempts from 1998 through 2003, Iwami et al¹⁸ found that 1 year survival with favorable neurologic outcome was similar for bystander-initiated cardiac-only resuscitation (4.3%; odds ratio [OR], 1.72; 95% confidence interval [CI], 1.01-2.95) and conventional CPR for most adult OHCA.

Olasveengen et al²⁰ did a retrospective, observational study between 2003 and 2006 in all non-traumatic cardiac arrest adult patients treated by the community-run emergency medical service (EMS)

in Oslo, Norway in which they measured outcomes for patients receiving Standard basic life support (S-BLS), compared with patients receiving only continuous chest compression (CCC). They found that there were no differences in outcomes between the two patient groups, with 13% discharged with a favorable outcome for the S-BLS group and 10% in the CCC group ($P = 0.85$). Similarly, there was no difference in survival subgroup analysis of patients presenting with initial VF/VT after witnessed arrest, with 29% and 28% patients discharged from hospital in the S-BLS and CCC groups, respectively ($P = 0.97$).

“LOOK, LISTEN, AND FEEL” HAS BEEN REMOVED FROM THE BLS ALGORITHM

Reasoning: “Look, listen, and feel” is an inconsistent and time-consuming practice. In a study by Rupert et al²¹ four different populations were tested for their ability to assess breathlessness: EMS personnel, physicians, medical students, and laypersons. Only 55.6% of all participants showed correct diagnostic skills. They concluded that this diagnostic procedure takes more time than recommended in international guidelines and checking for breathing was shown to be mostly inaccurate and unreliable. Professional as well as lay rescuers may be unable to accurately determine the presence or absence of adequate or normal breathing in unresponsive victims because the airway is not open or because the victim has occasional gasps.

1. A “chest compression rate of at least 100/min” is now recommended, different from the “approximately 100/min” recommended in 2005.

Reasoning: The number of chest compressions per minute is an important factor for attaining ROSC. Studies show that delivery of more frequent compressions is associated with better survival. A prospective observational study by Abella¹⁷ showed that in-hospital chest-compression rates were below published resuscitation recommendations; suboptimal compression rates were correlated with poor ROSC.

2. “Chest compression depth of at least 2 in (5 cm),” different from the “approximately 2 in” recommended in 2005.

Reasoning: Chest compression delivers blood flow and oxygen to heart and brain.

Studies show that rescuers often do not push hard enough. Steil et al²² found suboptimal compression depth in half of patients by 2005 guideline standards and in almost all patients by 2010 standards; a strong association between increased compression depth and higher survival outcomes was found.

3. If a bystander is not trained in CPR, it is recommended he/she perform hands-only CPR with the emphasis to push fast and hard at the center of the chest. AHA 2005 guidelines did not provide different recommendations for trained versus untrained rescuers. However, according to the N2010 AHA recommendations, the trained rescuer should perform cardiac compression and give breaths.

Reasoning: During the past 5 years, there has been an effort to simplify CPR recommendations and emphasize the fundamental importance of high-quality CPR. For most adults with OHCA, bystander CPR with chest compression only (Hands-Only CPR) appears to achieve outcomes similar to those of conventional CPR (compressions with rescue breathing).^{18,19} However, for children, conventional CPR is superior. Hands only CPR is easier for an untrained person. Studies written above^{19,20} show hands only CPR to be as effective as conventional CPR.

4. The new guidelines do not recommend routine use of cricoid pressure.

Reasoning: Cricoid pressure may impede ventilation and it can delay or prevent placement of an advanced airway, and some aspiration can still occur despite cricoid pressure. It is also difficult to train rescuers in using this maneuver. A study by Li et al²³ showed that cricoid pressure impedes insertion of, and ventilation

through the ProSeal laryngeal mask airway in anesthetized, paralyzed patients.

NEW RECOMMENDATIONS FROM 2010 AHA GUIDELINES FOR ADVANCE CARDIAC LIFE SUPPORT

ACLS is an extension of BLS and is implemented by a team which can provide advanced therapeutic care. At the time of the 2010 International Consensus Conference, there was still insufficient data to demonstrate that any drugs or mechanical CPR devices improve long-term outcomes after cardiac arrest. So the 2010 AHA Guidelines for CPR and ECC continue to emphasize that the foundation of successful ACLS is good BLS, beginning with prompt high-quality CPR with minimal interruptions, and for VF/pulseless VT, attempted defibrillation within minutes of collapse.⁷ The new recommendations focus on the Post-Cardiac Arrest Care, as comprehensive multidisciplinary care that begins with recognition of cardiac arrest and continues after ROSC, through hospital discharge and beyond.

1. Continuous quantitative waveform capnography is a major new Class I recommendation for intubated adults throughout the periarrest period. It should be used for confirming tracheal tube placement and for monitoring CPR quality and detecting return of spontaneous circulation, based on end-tidal carbon dioxide values.

Reasoning: Blood has to circulate through the lungs for carbon dioxide to be exhaled and measured, so capnography can be used for monitoring the effectiveness of chest compressions. Inadequate chest compressions, failing cardiac output, or rearrest causes decreased end tidal carbon dioxide. Grmec²⁴ studied adult patients intubated by an emergency physician in the field, with tube position confirmed by auscultation, infrared capnometry, and infrared capnography. He concluded that capnography is the most reliable method to confirm endotracheal tube placement in

emergency conditions in the prehospital setting

2. Atropine is not recommended for Pulseless electrical activity (asystole) while adenosine is recommended in the initial diagnosis and treatment of stable, undifferentiated, monomorphic tachycardia.

Reasoning: Evidence suggests that routine use of Atropine for PEA/Asystole is unlikely to have therapeutic benefit.⁷ Adenosine is safe and efficient and so recommended for aforementioned tachycardia.²⁵ The effects of atropine were assessed in 7448 adults with nonshockable rhythm from the SOS-KANTO study; they found that administration of atropine had no long-term neurological benefit in adults with OHCA due to nonshockable rhythm and concluded that atropine is not useful for adults with PEA.²⁶

3. Post-Cardiac arrest care to improve survival for victims of cardiac arrest admitted to hospital after return of spontaneous circulation. It should include cardiopulmonary and neurologic support, therapeutic hypothermia, and percutaneous coronary interventions when indicated; EEG for the diagnosis of seizures, monitored frequently in a comatose patient after ROSC; optimizing cardiopulmonary function and vital organ perfusion after ROSC; transportation to an appropriate hospital or critical-care unit with a comprehensive post-cardiac arrest treatment system of care; identification of and intervention for acute coronary syndromes; anticipation, treatment, and prevention of multiple organ dysfunction.

Reasoning: Systematically organized multidisciplinary treatment programs for post-cardiac arrest (in- or out-of-hospital) patients may improve survival to hospital discharge outcomes among victims who attain ROSC.²⁷ Coordinated programs focusing on optimizing neurologic, metabolic, and hemodynamic function have shown some promise when deployed in an integrated system of care. As of now, the individual effects of such therapies

have not been conclusively studied, but there is emerging evidence that use of such therapies may effectively improve outcomes. Studies have shown possible benefit of therapeutic hypothermia after cardiac arrest and that organized post-cardiac arrest care may improve survival to hospital discharge. Study done by hypothermia study group²⁸ found that therapeutic mild hypothermia increased the rate of a favorable neurologic outcome and reduced mortality for in-hospital patients who had been successfully resuscitated after cardiac arrest due to VF. It is recommended that post-cardiac arrest patient treated with therapeutic hypothermia be monitored for clinical neurologic signs using electrophysiological studies, biomarkers, and imaging where

available, at 3 days after cardiac arrest, to be used for prognostication.

The steps in BLS (shown in Figure 22-1) and ACLS (shown in Figure 22-2) are shown as algorithms to be followed.

EVIDENCE-BASED MEDICINE:
RECENT AND CONTROVERSIAL
TOPICS

Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients; the practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research.²⁹ Resuscitation research is particularly challenging because it must be scientifically

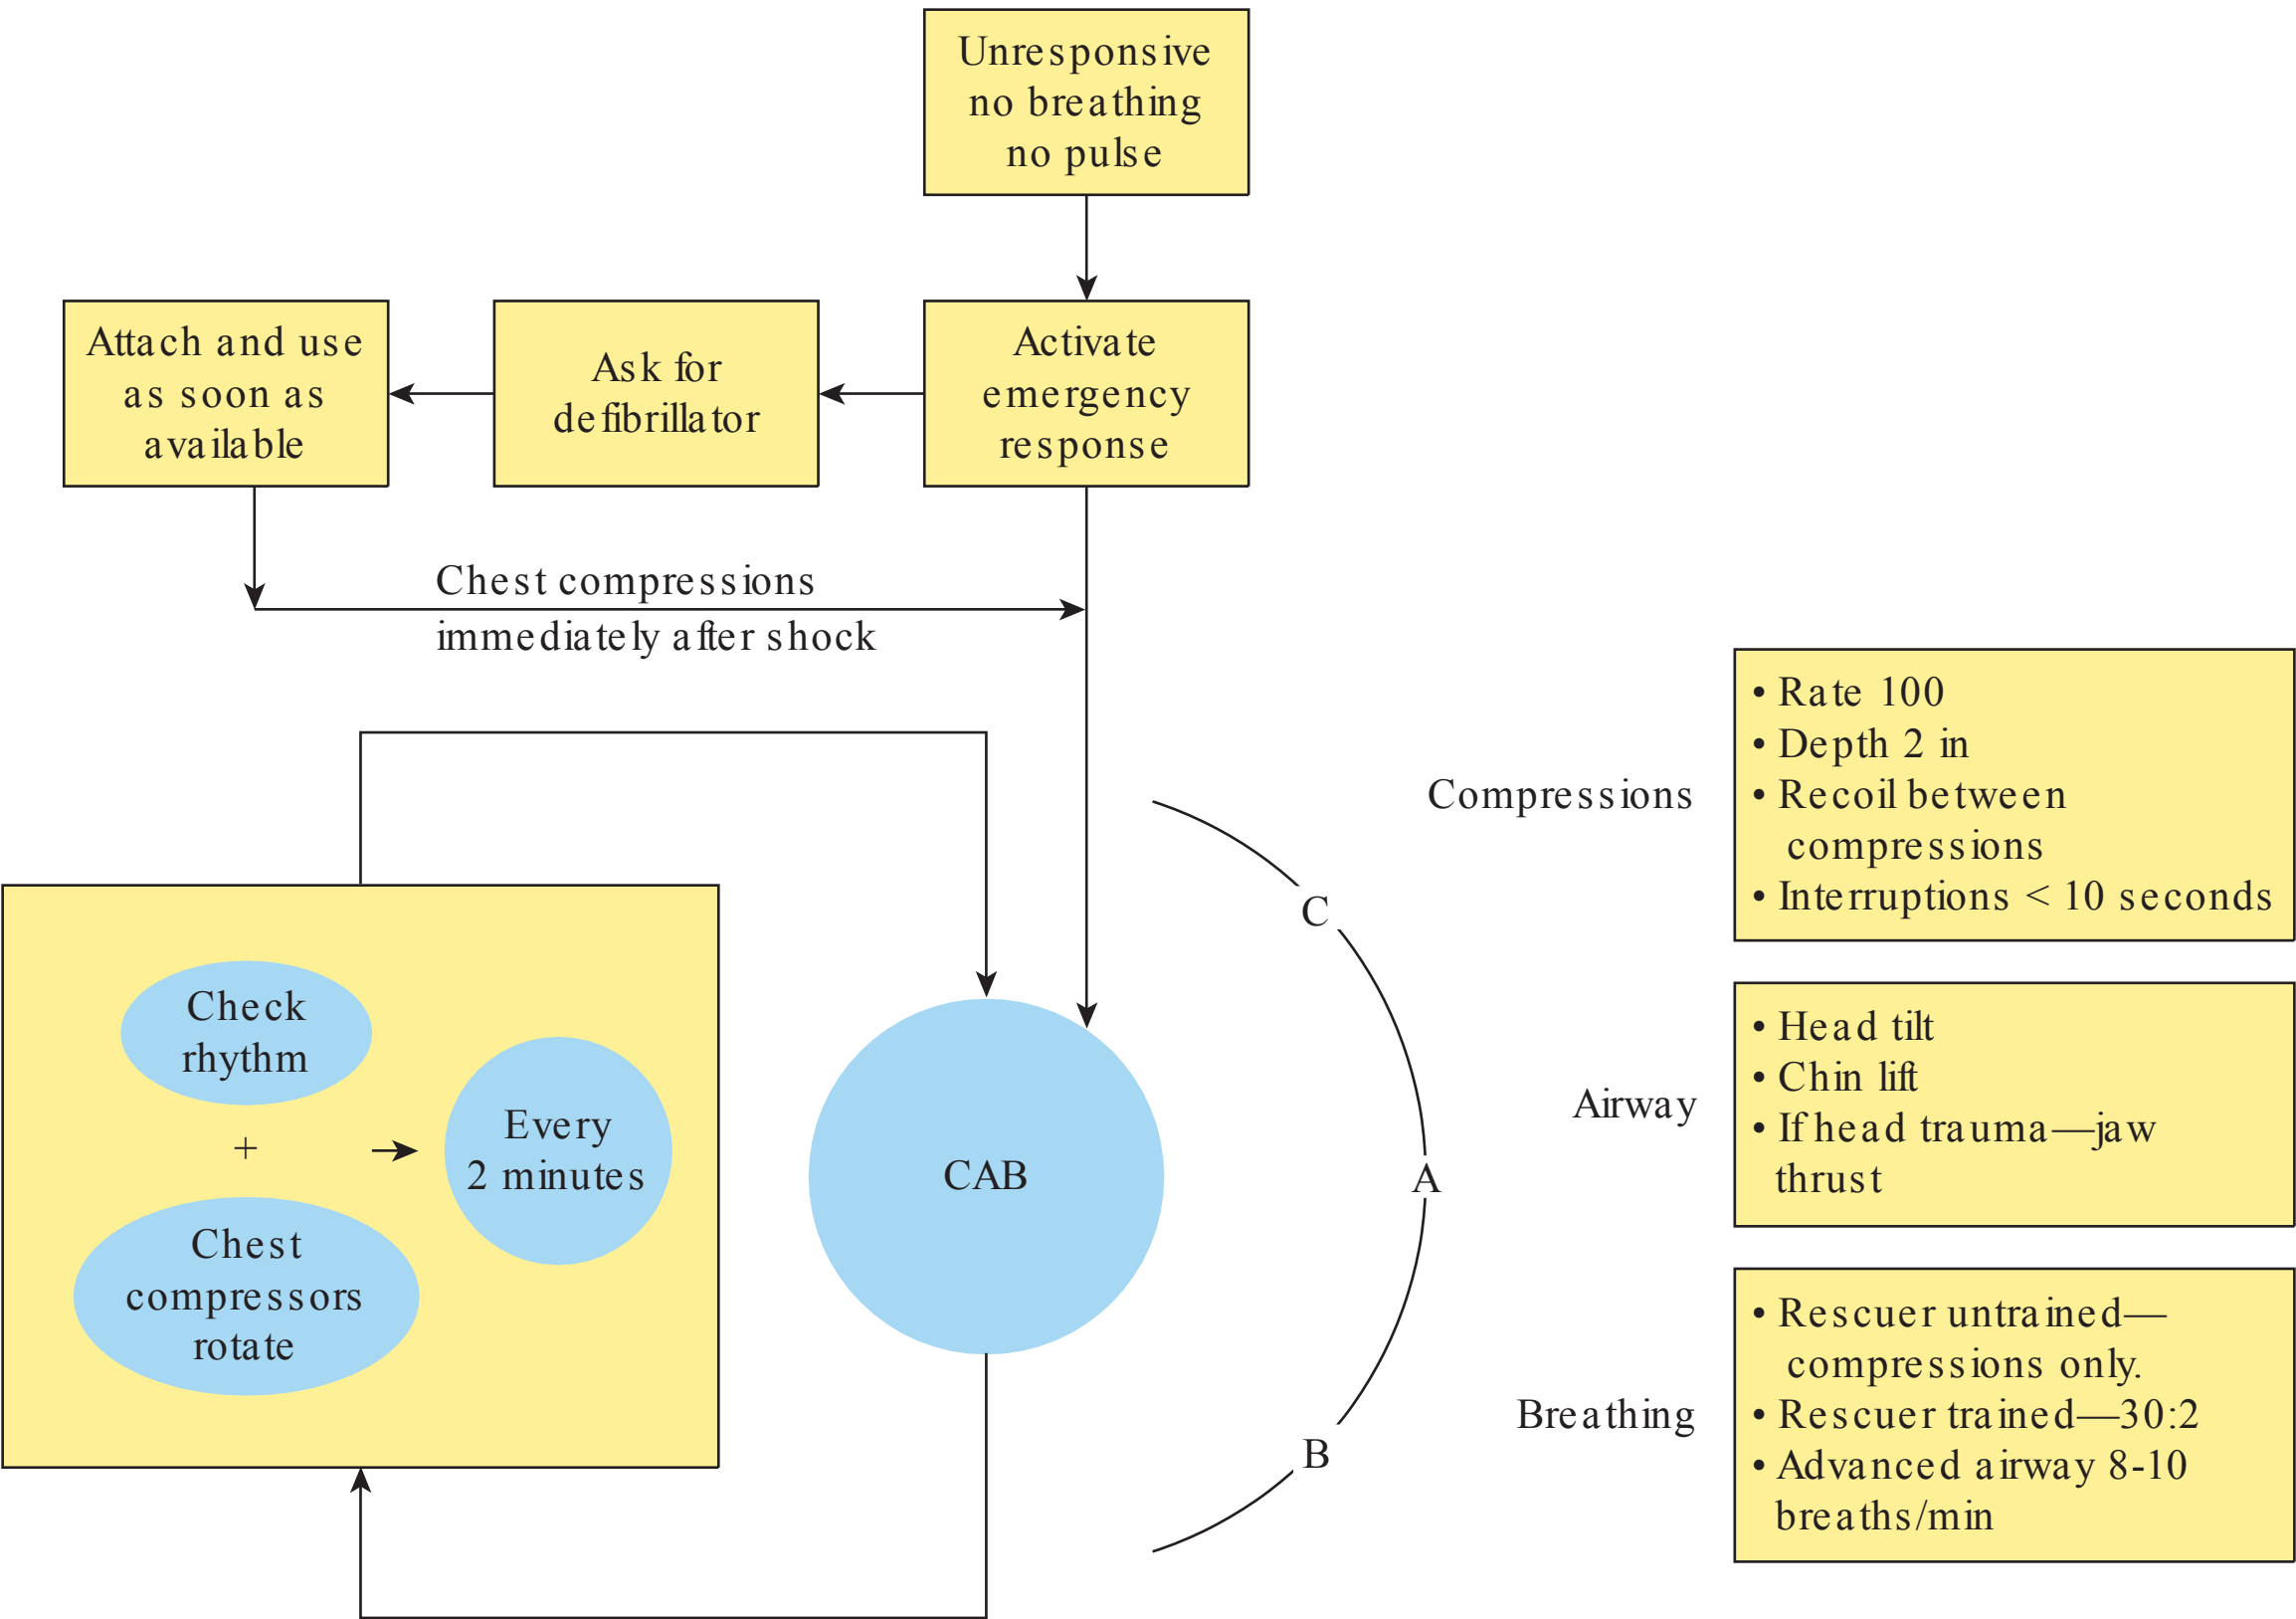

FIGURE 22-1 BLS algorithm.

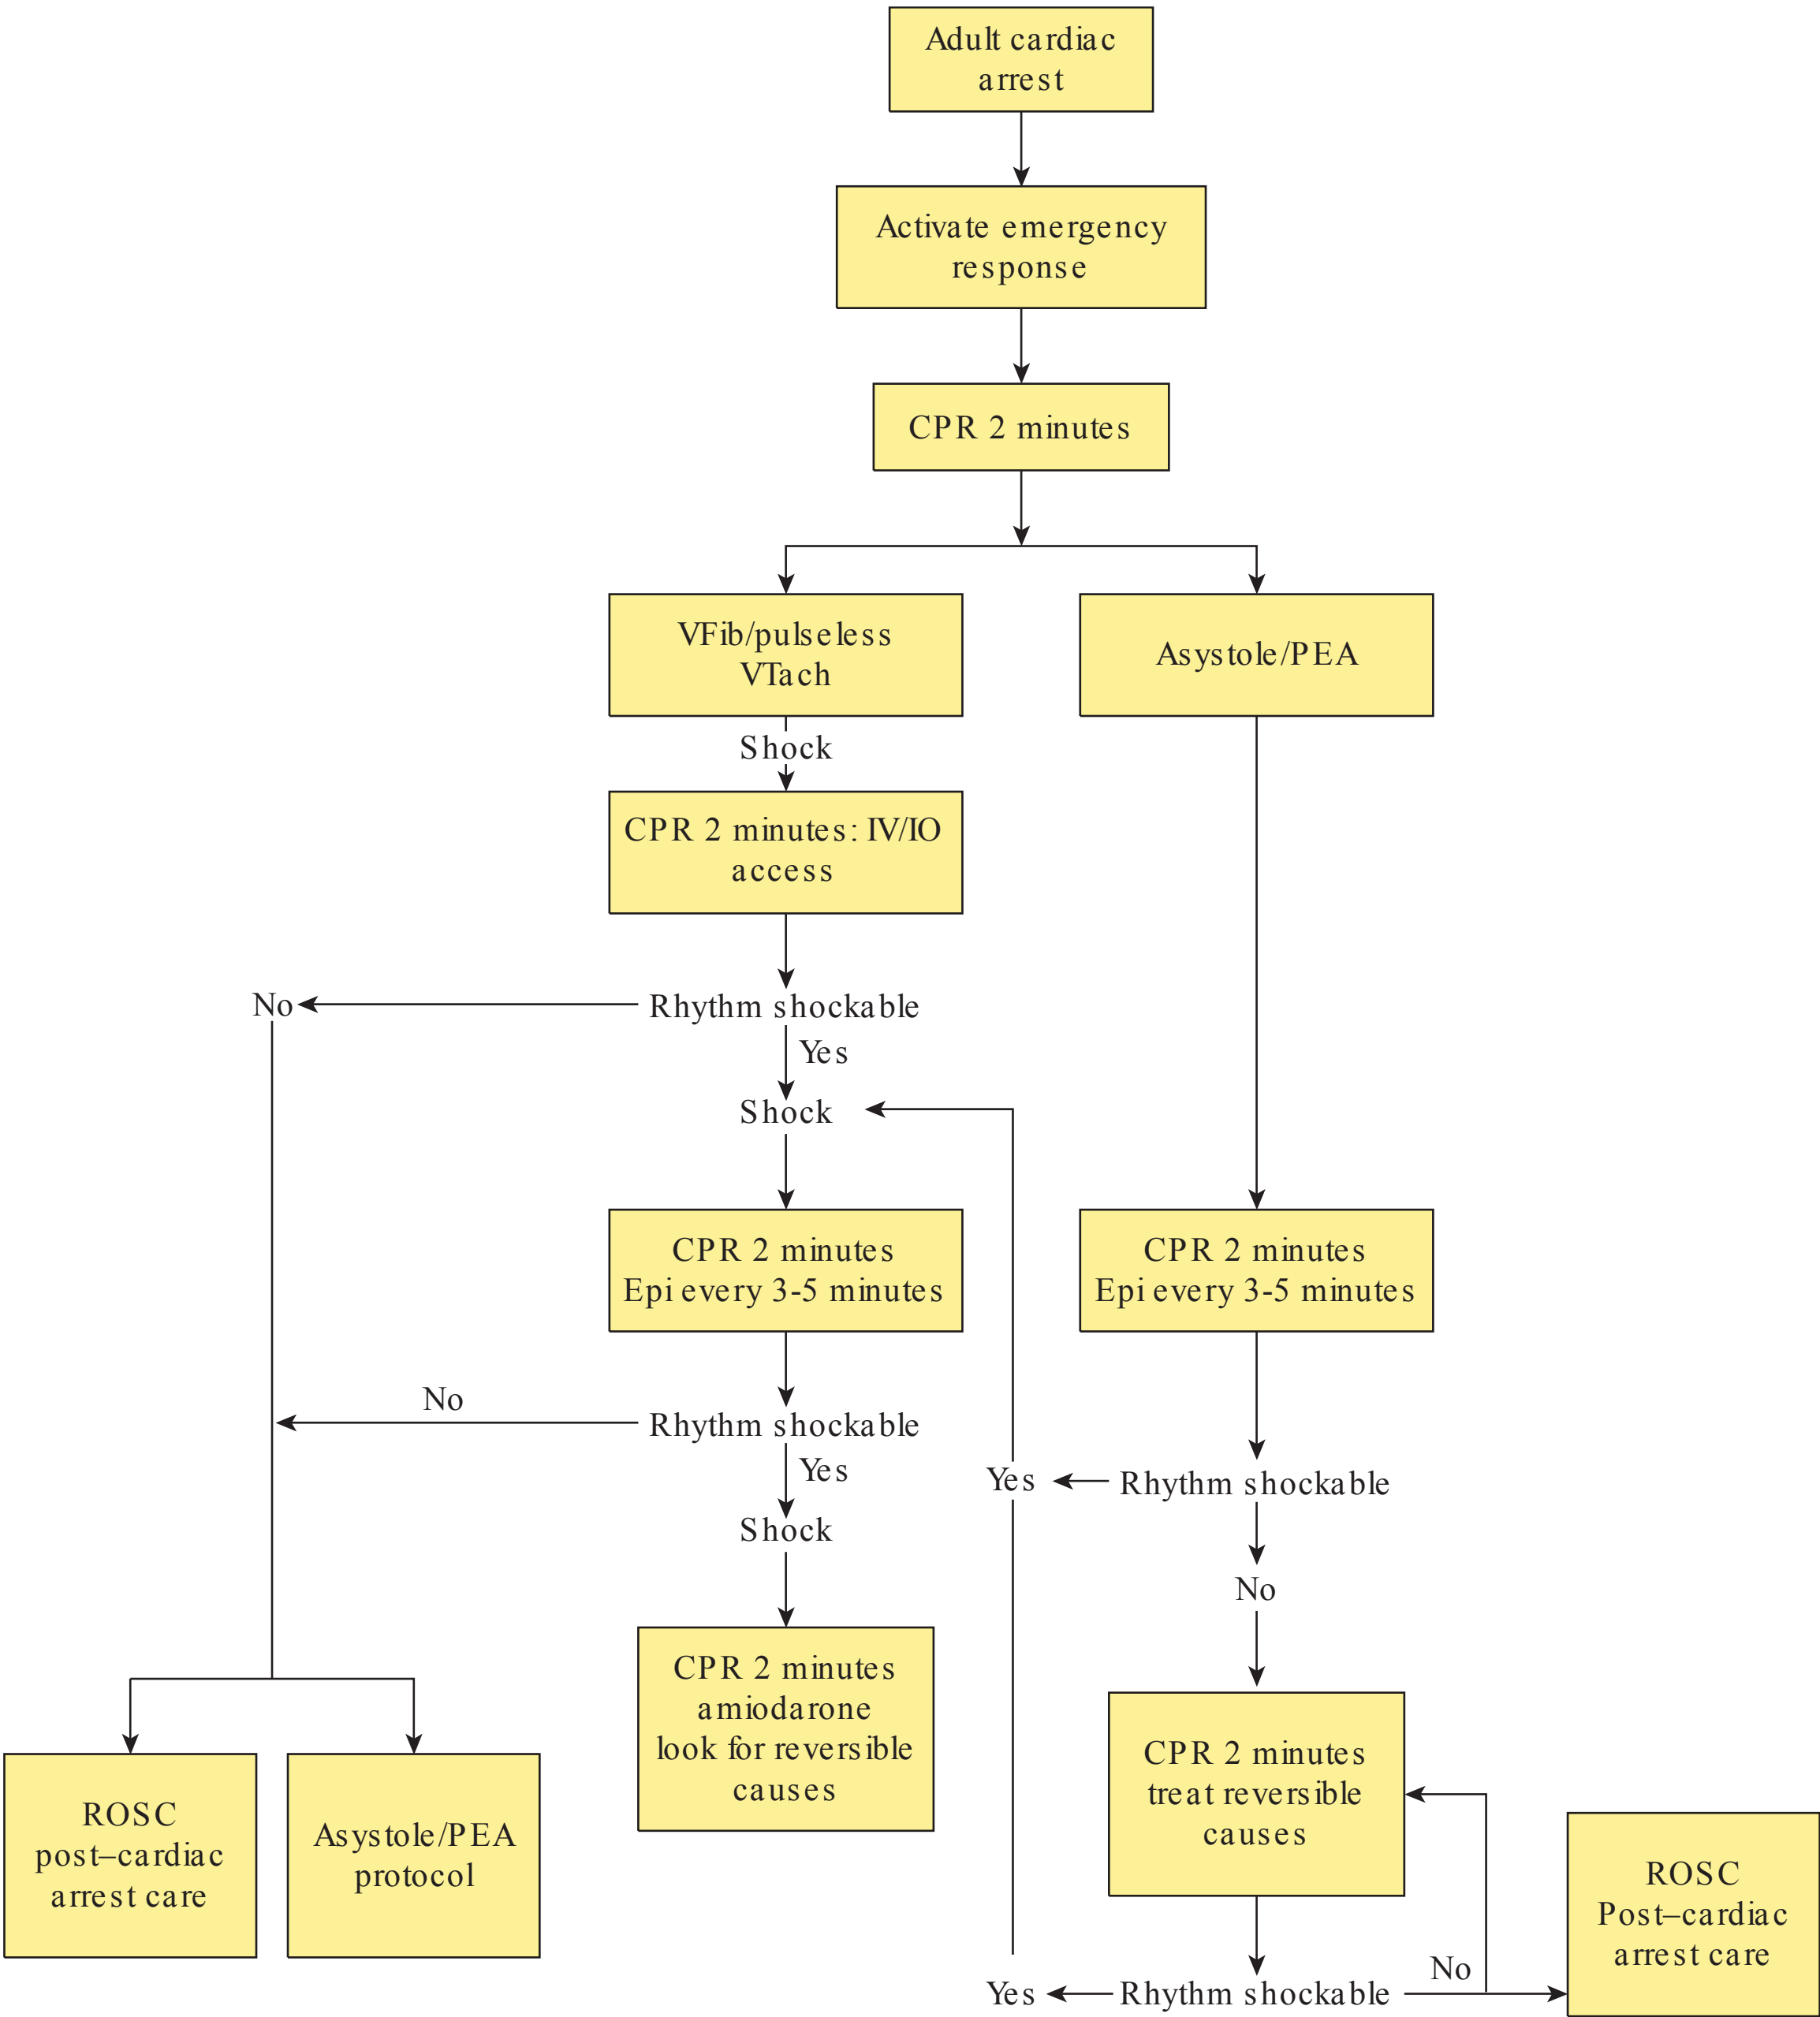

FIGURE 22–2 ACLS algorithm.

rigorous, while confronting ethical, regulatory, and public relations concerns that arise; life or death scenarios presented by the need for CPR make it impossible to receive informed consent from the patient. Regulatory requirements, community notification,

and consultation requirements often impose expensive and time-consuming demands that may not only delay important research, but also render it cost prohibitive, with little significant evidence that these measures effectively address the concerns about

research.³⁰ The following are some more recent and perhaps controversial topics/studies that arise when discussing evidence base CPR recommendations.

CPR OUTCOMES

Identifying the most accurate and relevant post-cardiac arrest outcomes to measure is a major challenge that requires further research. The most used measurements are survival to hospital discharge, or neurologically intact survival to discharge. Caution is advised, for example, when considering limiting care or withdrawing life-sustaining therapy because the predictors of neurological recovery currently in use have not been validated for patients who are treated with therapeutic hypothermia.

Hollenberg et al¹⁹ conducted a study during a 14 year time period (1992-2005) in Sweden describing changes in 1-month survival in patients given CPR after OHCA. He found improved survival rates over that time period; factors that potentially contributed to the improved survival rate were an increase in emergency medical crew-witnessed cases (from 9% in 1992 to 15% in 2005 [$P < 0.01$]) and, to a lesser degree, an increase in bystander CPR (from 31% in 1992 to 50% in 2005 [$P < 0.01$]).

Hinchey et al⁵ did an observational multiphase before-after cohort study to assess survival from OHCA in adult patients with cardiac arrest managed by emergency responders. They concluded that in the context of a community-wide focus on resuscitation, the sequential implementation of 2005 AHA guidelines for compressions, ventilations, and induced hypothermia significantly improved survival after cardiac arrest.

CPR Quality

Minimizing the interval between stopping chest compressions and delivering a shock (ie, minimizing the preshock pause) improves the chances of shock success and patient survival.³¹

Edelson et al³² did a study on internal medicine residents at a university hospital who attended weekly debriefing sessions of the prior week's resuscitations, reviewing CPR performance transcripts obtained from a CPR-sensing and feedback-enabled defibrillator. Compared with the control period, the

mean (SD) ventilation rate decreased (13 [7]/min vs 18 [8]/min; $P < 0.01$) and compression depth increased (50 [10] vs 44 [10] mm; $P < 0.01$), among other CPR improvements. These changes correlated with an increase in the rate of ROSC in the RAPID (Resuscitation with Actual Performance Integrated Debriefing) group (59.4% vs 44.6%; $P < 0.05$). They concluded that the combination of RAPID and real-time audiovisual feedback improved CPR quality compared with the use of feedback alone and was associated with an increased rate of ROSC. Survival from cardiac arrest depends on early recognition of the event and immediate activation of emergency response system, but equally critical is the quality of CPR delivered.

Five main components of high performance CPR have been identified: chest compression fraction (proportion of time chest compressions are administered in each minute of CPR), chest compression rate, chest compression depth, chest recoil, and ventilation.³³

CPR Devices

Several devices to provide effective CPR have been the focus of recent clinical trials. To date, no adjunct has consistently been shown to be superior to standard conventional (manual) CPR for out-of-hospital BLS, and no device other than a defibrillator has consistently improved long-term survival from OHCA.

Integration of AEDs into a system of care is critical in the Chain of Survival in public places outside of hospitals. To give the victim the best chance of survival, 3 actions must occur within the first moments of a cardiac arrest: activation of the EMS system, provision of CPR, and operation of a defibrillator.⁷ An area of continued interest is whether delivering a longer period of CPR before defibrillation improves outcomes in cardiac arrest. Early studies showed improved survival when 1.5 to 3 minutes of CPR preceded defibrillation for patients with cardiac arrest for more than 5 minutes duration prior to EMS arrival, but more recent trials did not improved outcomes.⁷

Transcutaneous pacing has also been the focus of several recent trials. In the current 2010 AHA recommendations, pacing is not generally recommended for patients in asystolic cardiac arrest since

randomized controlled trials indicate no improvement in rate of admission to hospital or survival to hospital discharge when pacing was attempted in patients with cardiac arrest in the prehospital or in-hospital (ED) setting.⁷

Medications Used During CPR

A meta-analysis of 5 randomized trials³⁴ showed no statistically significant differences between vasopressin and epinephrine for ROSC, 24-hour survival, or survival to hospital discharge.

It is appropriate to administer a 1-mg dose of epinephrine IV/IO every 3 to 5 minutes during adult cardiac arrest or one dose of vasopressin 40 U IV/IO may replace either the first or second dose of epinephrine in the treatment of pulseless arrest.⁷

Hypothermia

Therapeutic hypothermia is one intervention that has been shown to improve outcome for comatose adult victims of witnessed OHCA when the presenting rhythm was VF.²⁸ Since 2005, nonrandomized studies with concurrent controls or historic controls have indicated the possible benefit of hypothermia following in- and out-of-hospital cardiac arrest from all other initial rhythms in adults. Holzer's study found 53% survival with favorable neurological outcome in the endovascular cooling group, compared to 34% in the control group (OR 2.15, 95% CI, 1.38 to 3.35; $P < 0.05$).³⁵ Therapeutic hypothermia is a "game changer," changing the specificity of neurological prognostication decision rules that were previously established from studies of post-cardiac arrest patients not treated with hypothermia.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is a form of external cardiopulmonary life support (ECLS). Its goal is supporting the body's circulation in the absence of an adequately functioning cardiac pump. The initiation of ECLS and the management of a patient on ECLS require highly trained personnel and specialized equipment. ECLS has been associated with improved survival rates when compared with conventional CPR in patients less than 75 years old with potentially correctable conditions in case

series and observational studies for in-hospital and OHCA sufferers. Although there are no randomized studies that compare ECLS with conventional CPR for patients in cardiac arrest, there are data from several case series that demonstrate the feasibility and safety of ECLS in highly specialized centers,³⁶ but, as of this writing, there is not enough evidence to recommend the routine use of ECLS in this population.

Study by Thiagarajan³⁷ showed that ECMO used to support CPR rescued one third of patients in whom death was otherwise certain; improved survival was found in association with patient diagnosis, absence of severe metabolic acidosis before ECMO support, and uncomplicated ECMO course.

In a study by Lamhaut L et al³⁸ published in 2013, prehospital ECMO (PH-ECLS) was implemented by a PH-ECLS team for refractory cardiac arrest in 7 patients with a witnessed cardiac arrest, with CPR initiated within the first 5 minutes, and absence of severe comorbidities. This pilot study suggests that PH-ECLS performed by nonsurgeons is potentially safe and feasible. Further studies are needed to confirm the time saved by this strategy and its potential effect on survival.

Ethical Issues

1. Should resuscitative efforts be started? Ethical issues associated with CPR start with the question as to whether or not to initiate resuscitation as some patients might prefer palliative care without heroic measures to prolong life; advance directives play a very important role in these matters, and if an advance directive in the form of a living will is not available then a health care proxy or surrogate decision maker is helpful. Acknowledgment of a verbal or written do-not-attempt-resuscitation order may decrease the number of futile resuscitation attempts; however, there is insufficient evidence to support this without further validation.
2. When should resuscitative efforts stop? The final decision to stop resuscitative efforts often is not simple; clinical judgment and respect for patients' and their families' wishes must enter into decision making. Research addressing issues related to the appropriate termination

of resuscitative efforts is limited. Goto et al³⁹ performed a study with Japanese database on patients with OHCA. The main outcome measures were specificity, positive predictive value (PPV), and area under the receiver operating characteristic curve for the new developed termination of resuscitation (TOR) rule for emergency department physicians. They validated that the TOR rule consisting of 3 prehospital variables (no prehospital ROSC, unshockable initial rhythm, and unwitnessed by bystanders) had a more than 99% PPV of very poor outcome. However, the implementation of this new rule in other countries or EMS systems requires further validation studies.

3. Should family be present during CPR? Jabre P et al⁴⁰ enrolled 570 relatives of patients who were in cardiac arrest and were given CPR by 15 pre-hospital EMS units that were randomly assigned either to systematically offer the family member the opportunity to observe CPR (intervention group) or to follow standard practice regarding family presence (control group). The primary end point was the proportion of relatives with post-traumatic stress disorder-related symptoms on day 90; secondary end points included the presence of anxiety and depression symptoms, the effect of family presence on medical efforts at resuscitation, the well-being of the health care team, and the occurrence of medico-legal claims. They concluded that family presence during CPR was associated with positive results on psychological variables and did not interfere with medical efforts, increase stress in the health care team, or result in medico-legal conflicts. Some other studies indicate that no clear conclusion is derived from studies done so far and more studies have to be done in this area.
4. Organ donation. Because of the growing need for transplant tissue and organs, all provider teams who treat postarrest patients should also plan and implement a system of tissue and organ donation that is timely, effective, and supportive of family members for that subset of patients in whom brain death is confirmed or for organ donation after cardiac arrest.

EDUCATION AND IMPLEMENTATION

The 2010 AHA guidelines recommend education to improve the effectiveness of resuscitation.⁷ The recommendations include frequent practicing of skills; training of teamwork and leadership skills; formal training in CPR techniques, including compression-only (Hands-Only) in CPR to potential bystander rescuers; training in dispatcher instructions over the telephone by EMS providers. Recommended educational tools include high-quality medical simulators, videos, and written tests accompanied with a performance assessment.

CONCLUSION

The art of resuscitation has developed over thousands of years. The guidelines for resuscitation have had significant updates and as strong evidence-based studies continually provide the medical community with more information, methods used in resuscitative efforts may likely evolve further to improve patient outcomes. Extensive training and education of nonmedical staff in BLS and medical staff in BLS and ACLS is necessary so that we properly implement them. Simulation training on mannequins, for example, is one tool that can aid in the application of these guidelines effectively. Extensive studies have been done on CPR techniques but more research has to be done on the ethical and other aspects of CPR. We have come a long way in our understanding of what life-saving measures work best, and further understanding and evolution of CPR practices most likely will improve our ability to effectively save lives through CPR.

Arrhythmia Diagnosis and Management

Dipti Gupta, MD, MPH and Nancy Roistacher, MD

KEY POINTS

- 1 Between 12% and 19% of patients in intensive care unit (ICU) settings have sustained arrhythmias.
- 2 In the ICU, the most common causes of arrhythmias are infection, electrolyte abnormalities, medications, ischemia, anemia, hypoxia, and changes in volume status and hemodynamics.
- 3 Tachycardias are more common than bradycardias and atrial arrhythmias are more common than ventricular arrhythmias.
- 4 Common causes of bradycardia include beta-blockers, calcium channel blockers, digoxin, narcotics, and antiemetics.
- 5 Patients are less likely to remain hemodynamically stable with higher degrees of atrioventricular (AV) block and usually require temporary pacing (transthoracic or transvenous), and ultimately permanent pacing if the heart block persists.
- 6 AV dissociation occurs when there is loss of the usual pattern of atrial and ventricular synchrony and there is no association between P waves and the QRS complexes.
- 7 The majority of atrial tachyarrhythmias in the critically ill patient are due to atrial fibrillation, atrial flutter, AV nodal reentry tachycardia, ectopic atrial tachycardia with rapid ventricular rates, and underlying preexcitation with an atrial arrhythmia.
- 8 For the hemodynamically unstable or symptomatic patient with AV nodal reentrant tachycardia, initial choices include adenosine or direct current cardioversion to restore sinus rhythm and hemodynamic stability.
- 9 Multifocal atrial tachycardia is usually associated with underlying pulmonary disease especially severe chronic obstructive lung disease or respiratory failure in older, acutely ill individuals.
- 10 Atrial fibrillation is the most common dysrhythmia in the critically ill. Recent clinical trials have demonstrated similar outcomes with rate and rhythm control strategies for atrial fibrillation.
- 11 Indications for urgent cardioversion in atrial fibrillation include hypotension/shock, acute or ongoing myocardial ischemia, congestive heart failure and/or acute pulmonary edema, and underlying preexcitation with rapid ventricular rates and/or hemodynamic instability.
- 12 Torsade de pointes and other forms of polymorphic tachycardia are rapid ventricular rhythms associated with hemodynamic instability and

—Continued next page

Continued—

a predisposition to degenerate into ventricular fibrillation.

- 13** Patients with nonsustained ventricular tachycardias and ischemic heart disease in ICU settings should be given beta-blockers to control heart rate, blood pressure

and rhythm disturbances, electrolyte replacement, and control of stimulatory factors, such as anemia, pain, and fever.

- 14** Ventricular fibrillation requires emergency defibrillation.

INTRODUCTION

Acutely ill patients frequently have significant arrhythmias. By some estimates between 12% and 19% of patients in critical care unit settings have sustained arrhythmias.^{1,2} Patients following cardiac and thoracic surgery have a significant incidence of postoperative arrhythmias, specifically atrial fibrillation. Tachycardias are more common than bradycardias and atrial arrhythmias are more common than ventricular arrhythmias. Patients with underlying heart disease are more likely to have clinically significant arrhythmias. In the intensive care unit (ICU), multiple stimuli and associated elevated catecholamine levels contribute to arrhythmias. These include infection, electrolyte abnormalities, medications, ischemia, anemia, hypoxia, and changes in volume status and hemodynamics. Majority of these arrhythmias are secondary to at least one of these factors and usually respond to treatment of the primary medical or surgical processes.

Cardiac arrhythmias prolong the ICU length of stay of patients even if they are not the primary cause of their admissions and contribute to the morbidity and mortality of these patients. It is important to differentiate between those arrhythmias that need to be treated and those that are more benign so that a proper treatment plan can be instituted.

Tachycardias can be due to increased automaticity, reentry, or triggered activity. The stress seen in ICU patients can bring out or exacerbate underlying genetic or congenital predispositions, such as accessory pathways like Wolff-Parkinson-White Syndrome, Brugada syndrome, reentry

arrhythmias, and congenital long QT syndromes. When assessing 12-lead electrocardiograms (EKG), monitor strips and a careful physical examination are important in addition to looking for structural heart disease.

Myocardial dysfunction, valvular abnormalities, pericardial disease, congenital heart disease, and conduction abnormalities may be present. Acute cardiac dysfunction due to sepsis or related to high catecholamine states (Takotsubo syndrome) should also be considered in these critically ill patients.

The hemodynamic stability of the patient also needs to be assessed in addition to blood test analysis, medication lists, and EKG and telemetry analysis. Electrolyte abnormalities and renal or hepatic failure can be contributory. The presence of hemodynamic compromise or associated ischemia indicates the need for acute intervention. Reversible factors should be identified and treated. Significant prolongation of the QT interval is likely due to electrolyte abnormalities, such as hypomagnesemia and hypokalemia or to medications. The use of inotropes and vasopressor agents can increase heart rate (HR) and induce tachyarrhythmias. Fever, respiratory failure and severe anemia can also be contributing factors.

BRADYARRHYTHMIAS

Increased vagal tone can slow HR and sometimes can cause delays in cardiac conduction. Medications used to control blood pressure and tachyarrhythmias can cause further delays in conduction and heart block in patients with underlying conduction system

disease. Beta-blockers, calcium channel blockers, digoxin, narcotics, and antiemetics can cause bradycardia and sometimes higher degree atrioventricular (AV) block. Bradycardia rarely needs to be treated unless there is associated hemodynamic instability.

Progressive delay in conduction of intracardiac electrical impulses can occur. Isolated first-degree AV block with prolongation of the PR interval to more than 200 ms does not need treatment although it can be associated with other conduction abnormalities. Second-degree AV block occurs when not all sinus impulses are transmitted to the ventricle. In Mobitz type I (Wenckebach) second-degree AV block there is progressive lengthening of the PR interval with constant P-P intervals eventually

leading to nonconducted P waves in a pattern of group beating (ratio of P waves to QRS complexes). This is usually due to a reversible delay of conduction in the AV node and is likely due to increased vagal tone or medications. It rarely needs treatment unless there is severe bradycardia and associated hypotension. Mobitz type II second-degree AV block, high-degree block, and complete heart block involve varying degrees of delay in the infranodal conduction system and are usually due to intrinsic conduction system disease. A lower ventricular escape rhythm with a rate of 25 to 40 beats/min is often present in complete heart block in an attempt to maintain cardiac output but may not provide an adequate HR ([Figure 23–1a](#)). Patients are less likely

(a)

(b)

FIGURE 23–1 (a) A 12-lead electrocardiogram with atrioventricular dissociation with severe sinus bradycardia and an idioventricular escape rhythm of 43 beats/min with left bundle branch conduction. (b) Monitor strip showing atrioventricular dissociation with an underlying sinus rhythm of 70 beats/min and a monomorphic ventricular tachycardia.

to remain hemodynamically stable with higher degrees of AV block and usually require temporary pacing with either a transthoracic or transvenous pacemaker and ultimately permanent pacing if the heart block persists. While atropine increases HR by decreasing vagal tone and the degree of AV block with type I AV block, it is usually ineffective in increasing HR with infranodal conduction delays and may actually increase the degree of block by increasing sinus rate without the ability to increase ventricular rate. Another common cause of bradycardia in the ICU occurs in patients with alternating bradycardia and tachyarrhythmias (Tachy-Brady syndrome) or paroxysmal atrial fibrillation, who have delayed sinus node recovery times either due to intrinsic conduction system disease or to the medications used to control the tachycardia. They can have prolonged pauses when they convert to sinus rhythm and may require pacing to allow adequate medication to control their arrhythmia without periods of symptomatic bradycardia.

AV dissociation occurs when there is loss of the usual pattern of atrial and ventricular synchrony and there is no association between P waves and the QRS complexes. This can be caused by heart block as discussed earlier where impulses cannot be transmitted through the AV node and a lower focus (escape rhythm) takes over (Figure 23-1a). Persistent heart block usually leads to permanent pacemaker implantation. A benign form of AV dissociation is called isoarrhythmic AV dissociation (Figure 23-2), which occurs when the sinus rate is slower than or approximately the same as a lower intrinsic cardiac rhythm so the rhythms alternate. This is commonly a junctional rhythm of 50 to 60 beats/min and does not need treatment unless there is associated hemodynamic instability. Isoarrhythmic AV dissociation resolves with an increase in the sinus rate. Acceleration of a lower focus such as a junctional or ventricular tachycardia can also cause AV dissociation. These rhythms usually require treatment if sustained or symptomatic.

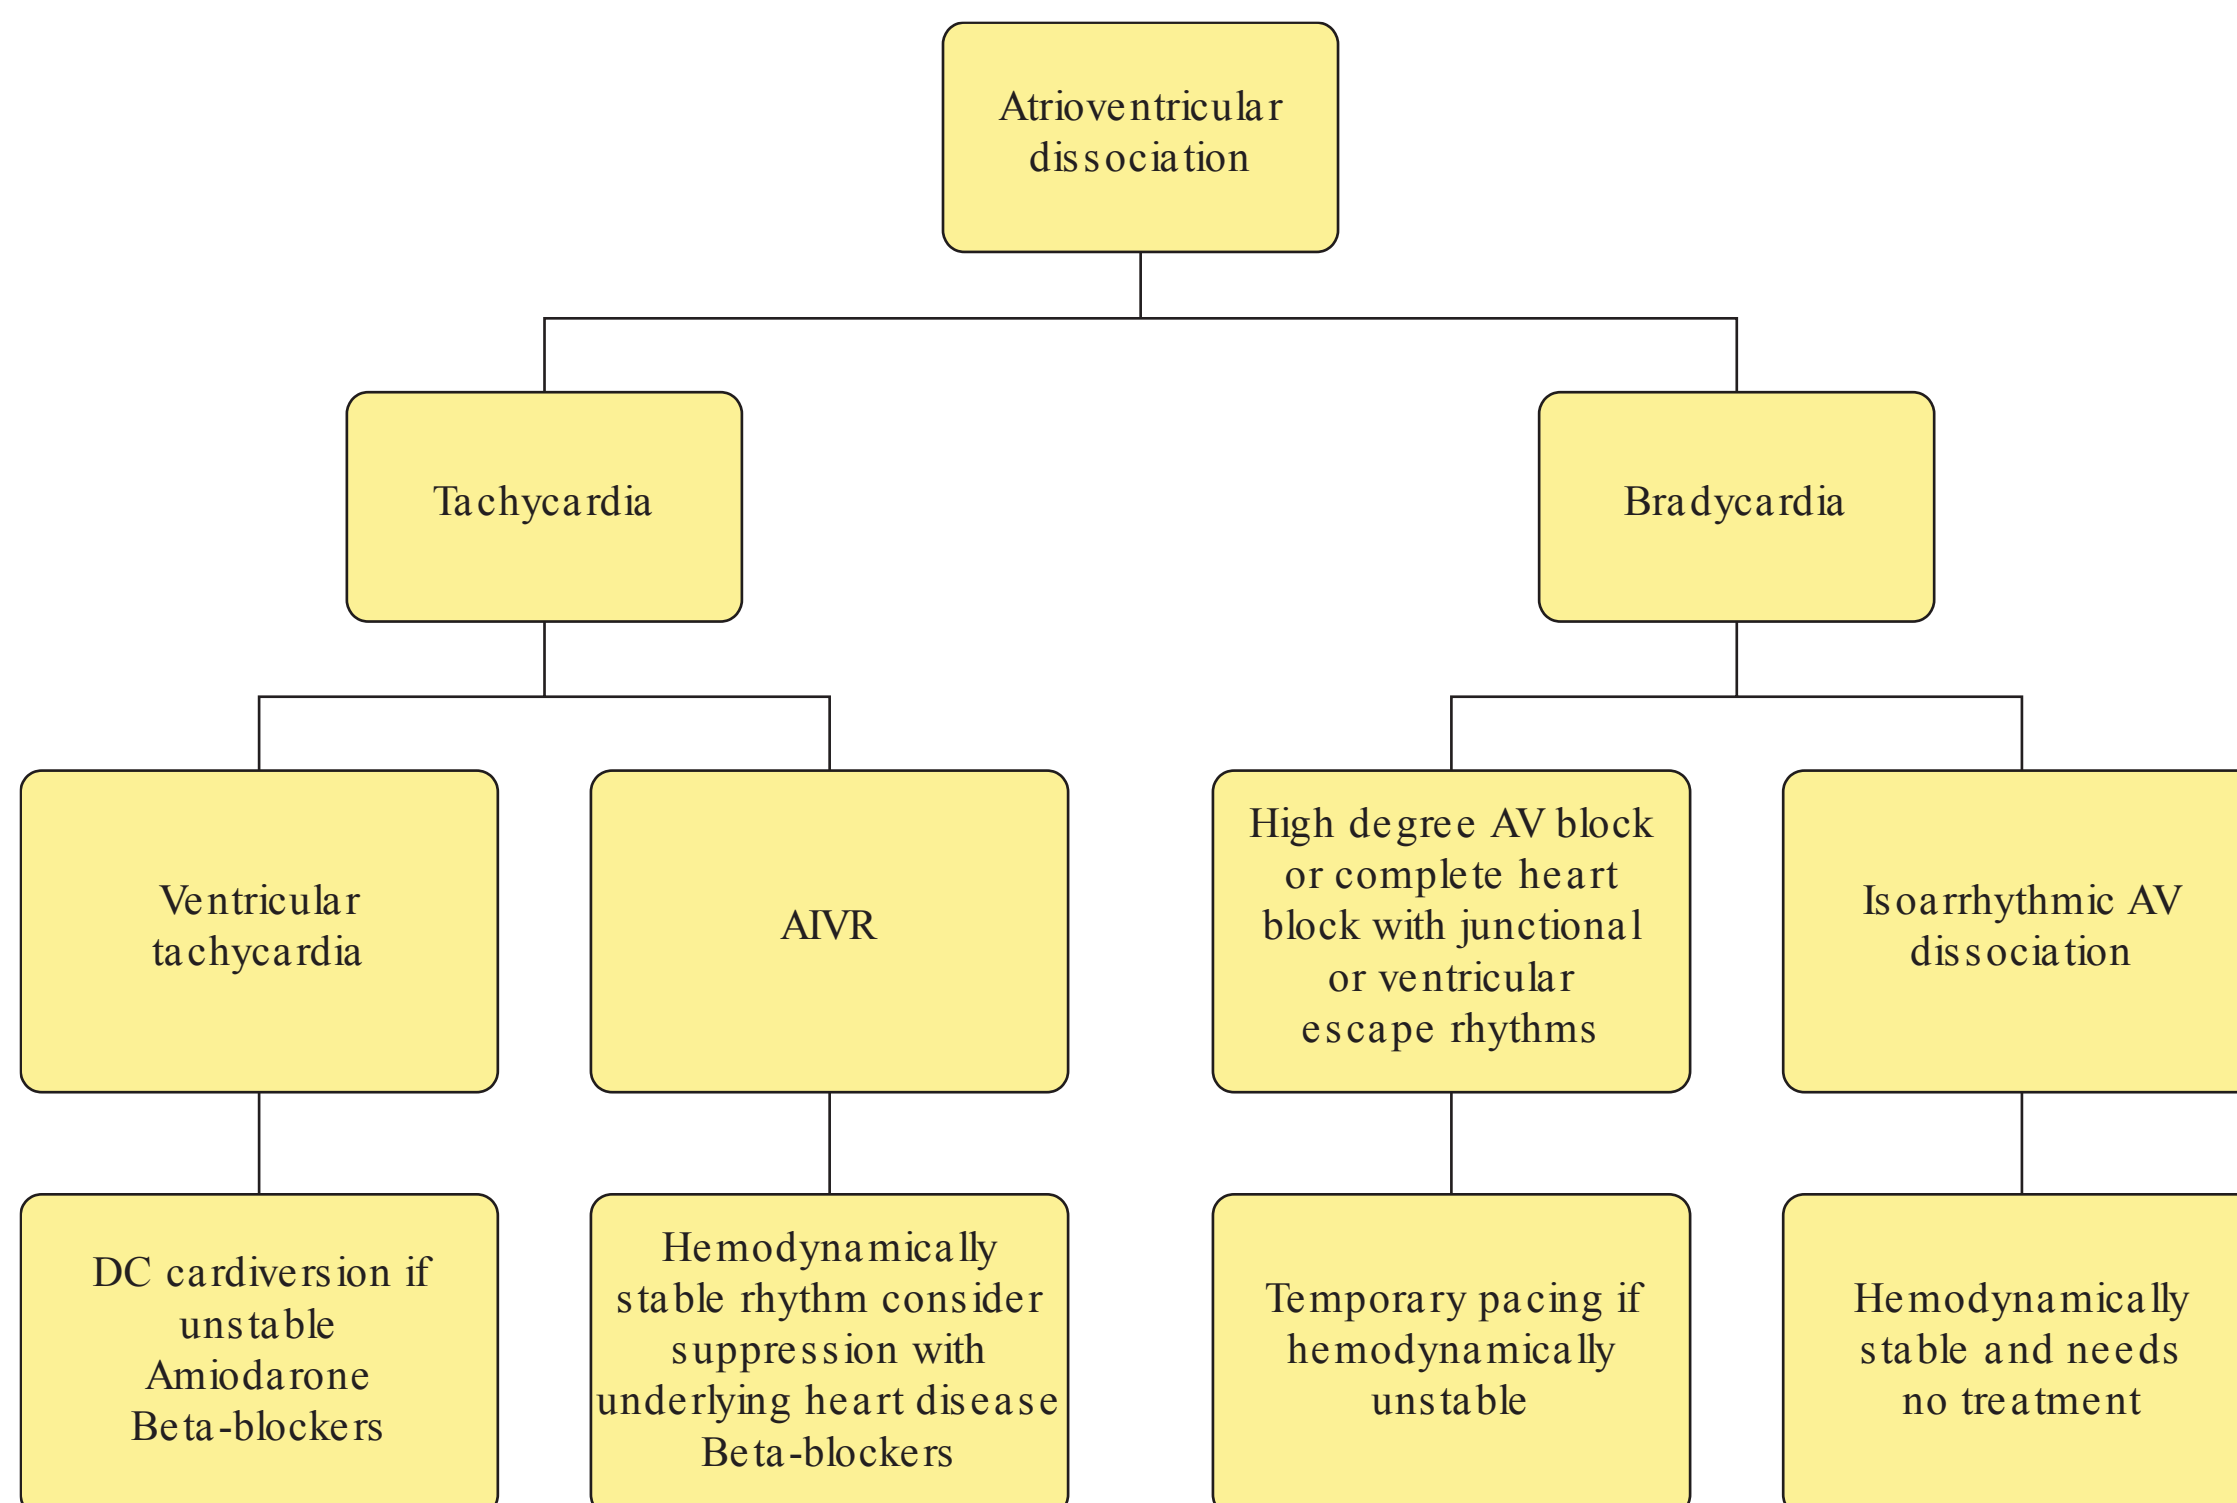

FIGURE 23-2 Differential diagnosis and treatment of atrioventricular dissociation.

TACHYARRHYTHMIAS

ICU patients frequently have atrial and ventricular beats, which rarely need to be treated unless there is a sustained arrhythmia. Even frequent ventricular premature contractions (VPCs) with couplets, periods of bigeminy, and short runs do not need treatment unless the cardiac output is compromised. Underlying provocative causes, such as ischemia, left ventricular dysfunction, medication toxicity (eg, digoxin), or electrolyte abnormalities should be identified and addressed.

Sustained arrhythmias are less frequent but not uncommon. It is usually possible to differentiate between atrial and ventricular arrhythmias, but one of the biggest challenges in critically ill patients is to define the etiology of a wide complex tachycardia. Knowledge of the baseline EKG is important to help differentiate these arrhythmias. Patients with baseline right or left bundle branch blocks (LBBBs) have wide complex tachycardias, which are supraventricular with a QRS morphology that is the same as their baseline EKGs and are usually preceded by P waves. Some patients develop rate-related bundle branch blocks usually with an increase in HR that can cause confusion, but similarly are supraventricular, usually sinus in origin and due to variable delay in the conduction system and refractory periods of the bundle branches. Another form of wide complex supraventricular tachycardia can occur in patients

with preexcitation syndromes when there is orthodromic conduction down the accessory pathway. These forms of supraventricular tachycardias need to be differentiated from ventricular rhythms.

The morphology of the QRS complexes can help differentiate supraventricular from ventricular rhythms. Ventricular tachycardias, while more likely to have LBBB configurations, have varying conduction patterns, have longer QRS durations ($> 0.14\text{--}0.16$ ms) and have greater leftward axis deviation. Evidence of AV dissociation with fusion or capture beats usually indicates a lower origin of the arrhythmia such as ventricular tachycardia.

SUPRAVENTRICULAR TACHYCARDIAS

Atrial fibrillation, atrial flutter, AV nodal reentry tachycardia, ectopic atrial tachycardia with rapid ventricular rates, and underlying preexcitation with an atrial arrhythmia form the majority of atrial tachyarrhythmias that manifest in the critically ill patient. [Figure 23–3](#) lays out a classification scheme for narrow complex supraventricular tachycardias based on the regularity of the rhythm.

Initial evaluation is directed toward assessing hemodynamic stability. In the setting of hemodynamic compromise (eg, symptomatic hypotension, angina, heart failure, or myocardial ischemia) urgent

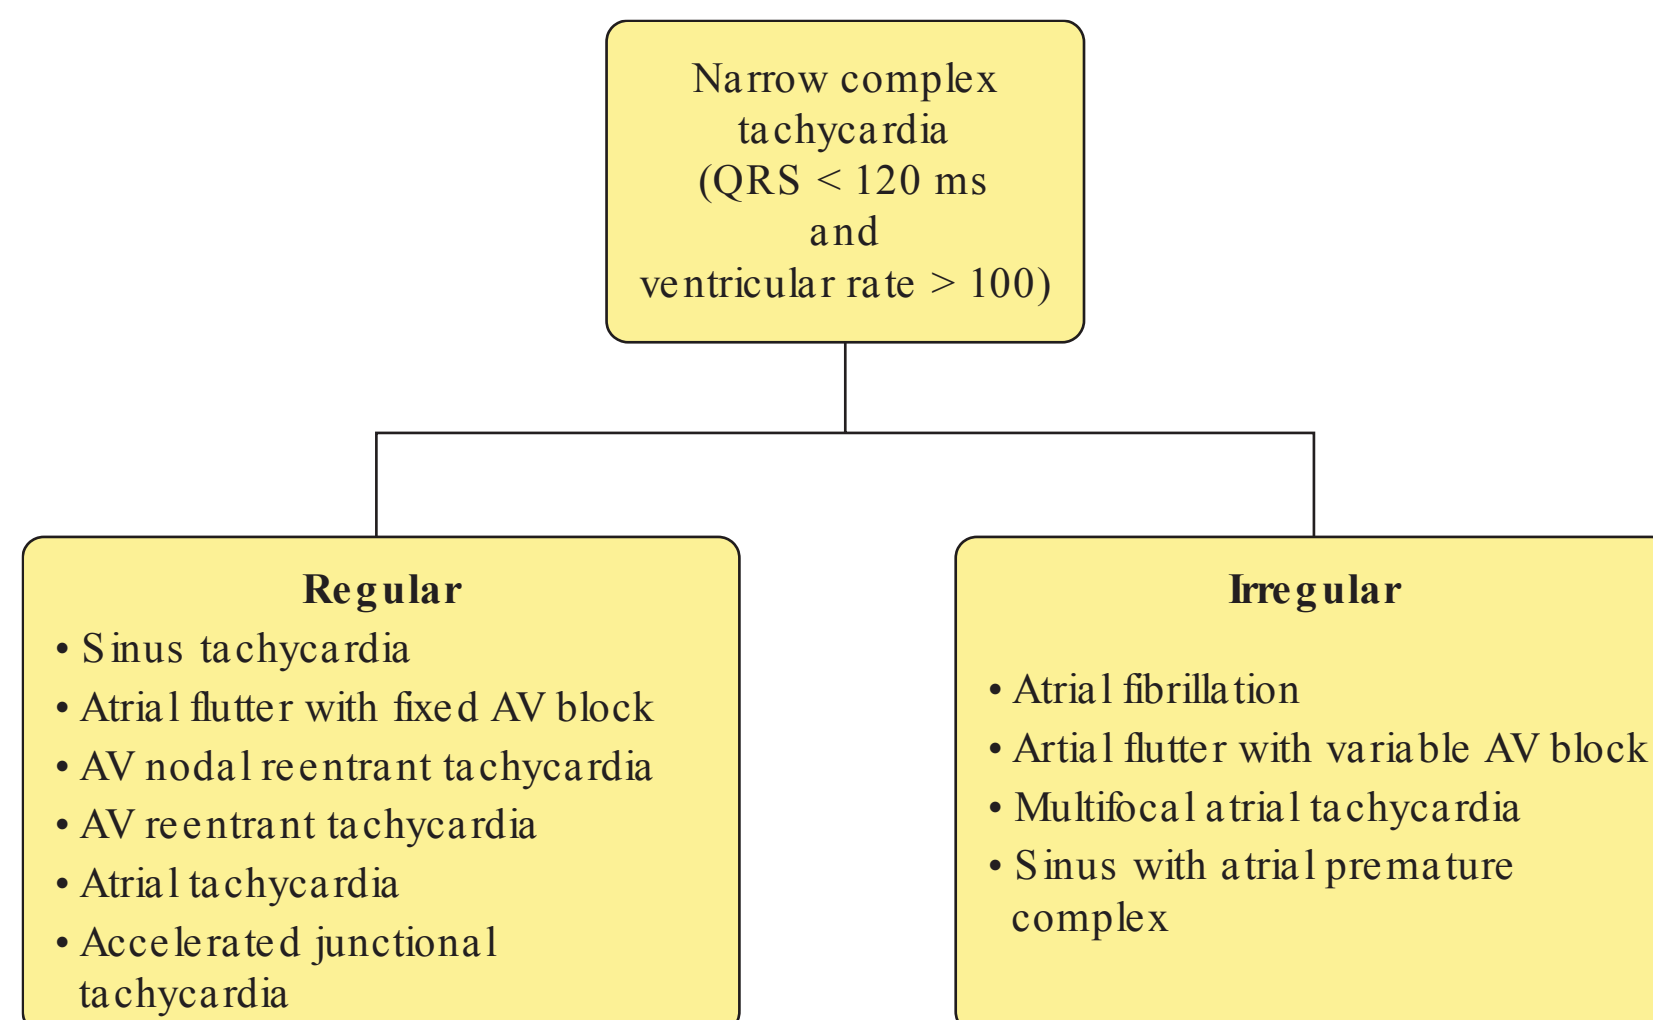

FIGURE 23–3 Classification of narrow complex tachycardias.

electrical cardioversion is indicated. The major goal of acute treatment is to slow the ventricular rate so as to restore hemodynamic stability by improving cardiac output and blood pressure. For patients that are hemodynamically stable, initial rate control strategy should be considered. Further treatment is directed toward eliminating or reversing the precipitating or exacerbating causes. Correction of alkalosis, hypokalemia, hypomagnesemia, and hypoxemia will increase the likelihood of rate control and eventual conversion to or maintenance of sinus rhythm.

ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

About 65% of regular supraventricular tachycardias are due to atrioventricular nodal reentrant tachycardia (AVNRT).³ AV nodal reentrant tachycardias are rhythm disturbances that depend on the properties of the AV node for initiation and propagation. In a typical circuit, activation proceeds down the antero-
grade “slow” pathway and returns via the retrograde “fast” pathway. The arrhythmia results from an endless circle of electrical impulses conducted down one

pathway and up another with slow and fast pathways cooperating to facilitate and maintain the circuit. The atypical form of AVNRT involves antegrade conduction down the “fast” perinodal pathway and retrograde conduction via the “slow” perinodal pathway. AV nodal reentrant tachycardias usually have ventricular rates of 150 to 220 beats/min, but can be as fast as 250 beats/min. AV conduction is usually 1:1, but rarely 2:1. It usually begins with a premature atrial depolarization. There can be a pseudo R’ in lead V1, a pseudo-S wave in the inferior leads and retrograde P wave can be seen in other leads. If the initial diagnosis is unclear, adenosine (6-12-12 mg intravenously) usually will break the reentry circuit and restore sinus rhythm (Figure 23-4). A brief intervening period of sinus bradycardia or complete heart block may occur. With atrial tachycardia, atrial flutter, or atrial fibrillation, increasing AV block with adenosine will usually make the diagnosis apparent while with sinus tachycardia the heart will slow gradually in response to adenosine and then return to the pretreatment rate.

For the hemodynamically unstable or symptomatic patient with AVNRT, initial choices include

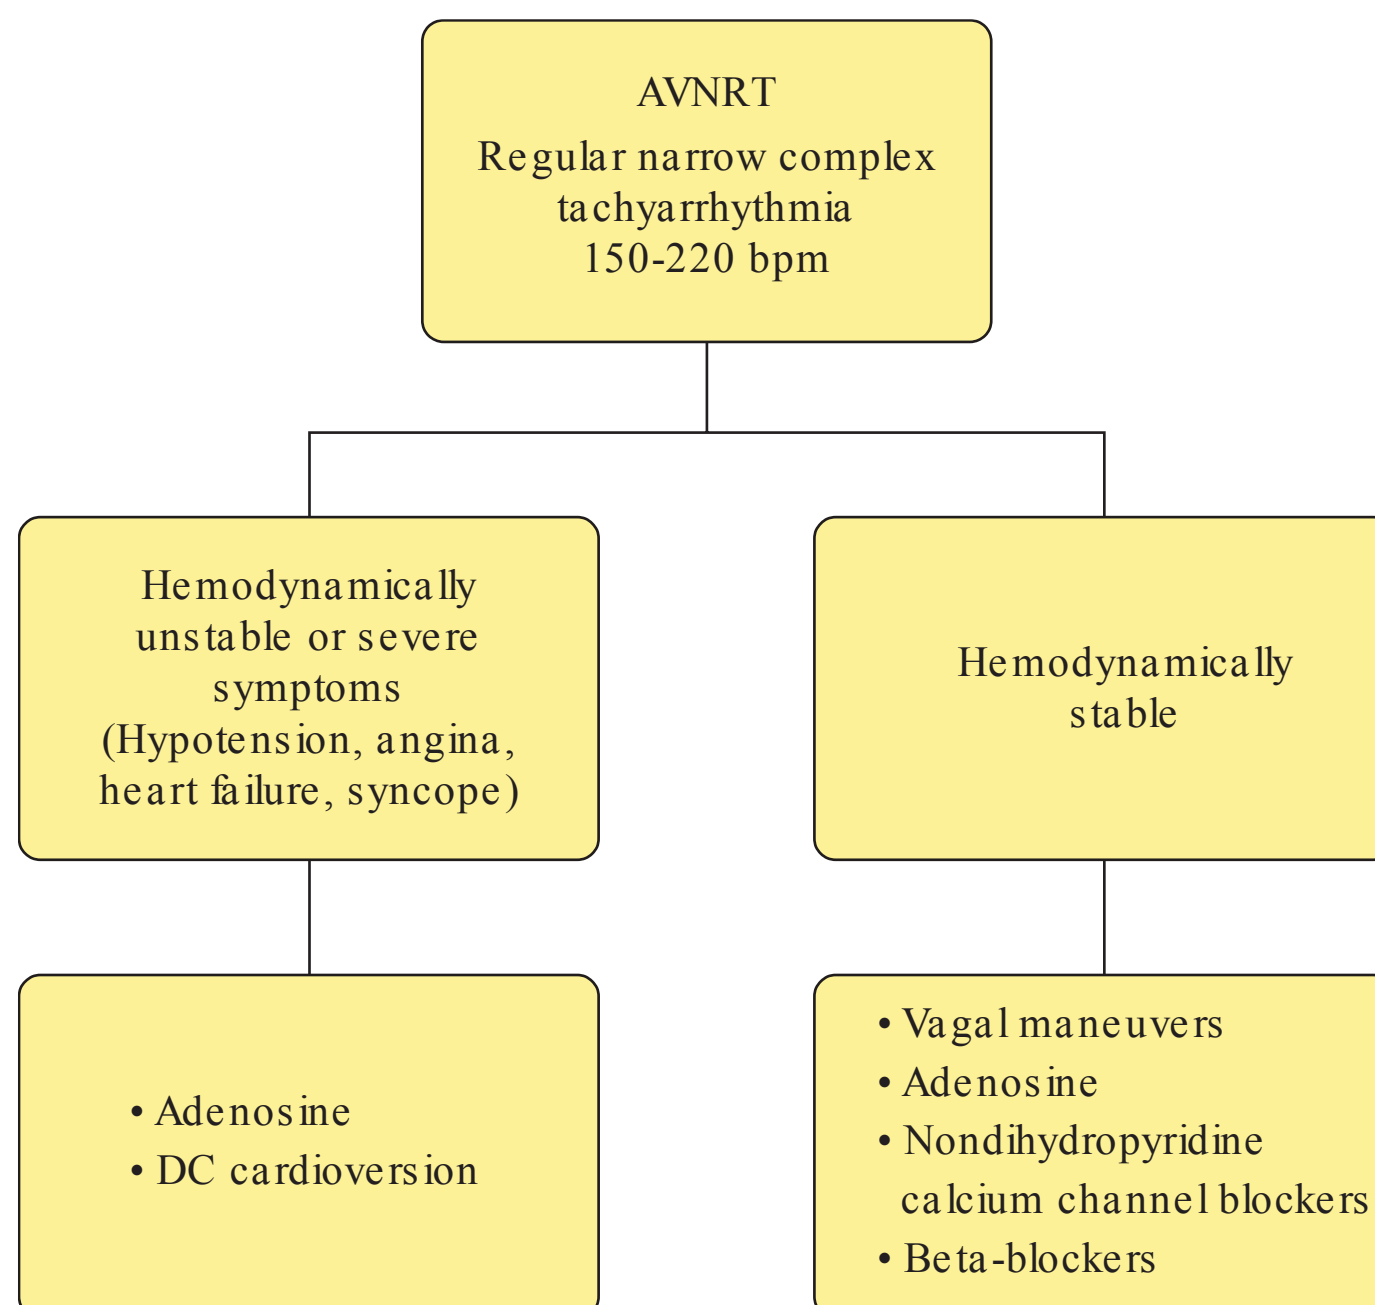

FIGURE 23-4 Management of AVNRT.

adenosine or direct current (DC) cardioversion to restore sinus rhythm and hemodynamic stability. Adenosine has a rapid onset and an extremely short half-life, making it the drug of choice for acute treatment of narrow complex tachyarrhythmias, but it is not useful in preventing recurrences.

For the hemodynamically stable patient, treatment approaches include vagal maneuvers (eg, Valsalva maneuver or carotid sinus massage), adenosine, nondihydropyridine calcium channel blockers (eg, verapamil 5 mg IV bolus or diltiazem 0.25 mg/kg infusion given over 2 minutes) and beta-blockers (eg, metoprolol with 5 mg boluses or esmolol, 0.5-1.0 mg/m² bolus). These drugs alter conduction velocity through the AV node (see Figure 23-4). Calcium channel blockers and beta-blockers decrease the likelihood of recurrence and should be considered in patients with early recurrent arrhythmia after administration of adenosine. Continued intravenous (IV) infusions may be needed to prevent early recurrences. For long-term management of patients with symptomatic episodes of this tachyarrhythmia, options include pharmacologic therapy and radiofrequency catheter ablation with the latter providing high curative success rates.

ATRIAL TACHYCARDIA

Atrial tachycardia is a narrow complex tachyarrhythmia with impulse generation outside of the sinus node that does not rely on accessory pathways, AV node, or ventricular tissue for generation and propagation.³ Atrial tachycardia is usually focal in origin and can arise from any ectopic focus in the left atrium, right atrium, vena cava, or pulmonary veins. The underlying mechanism can involve reentry, enhanced automaticity, or triggered activity. Atrial tachycardia may occur from atrial stretch, digitalis toxicity, electrolyte imbalance, and catecholamine excess with or without underlying cardiac disease. On the EKG, the P wave generally precedes the QRS complex; however, it has a morphology that is distinct from the sinus P wave. The P wave axis is usually abnormal and may help in localizing the site of origin of the tachycardia. AV nodal blockers and digoxin do not terminate this arrhythmia, but can be used to slow down the ventricular rate and improve hemodynamics. In select cases, there may

be a role for class Ia, Ic, or III antiarrhythmic agents. Electrical cardioversion plays a limited role in the management of atrial tachycardia as the underlying pathophysiology is usually enhanced automaticity, which in most cases renders cardioversion ineffective with a high rate of arrhythmia recurrence.

MULTIFOCAL ATRIAL TACHYCARDIA

Multifocal atrial tachycardia is usually associated with underlying pulmonary disease especially severe chronic obstructive lung disease or respiratory failure in older, acutely ill individuals.³ It can also occur in patients with other forms of pulmonary or cardiac disease. Electrolyte imbalance, hypoxia, acidosis, and drugs, such as isoproterenol and theophylline are also associated with this arrhythmia. It is characterized by an irregularly irregular rhythm with a ventricular rate greater than 100 beats/min and at least 3 unique P-wave morphologies each felt to indicate multiple atrial activation sites. Treatment is aimed at the underlying disease. Verapamil may be effective and sometimes slows ventricular response, but is not effective in all patients.

ATRIAL FLUTTER

Atrial flutter is a macroreentrant atrial tachycardia typically involving the right atrium. It usually coexists with atrial fibrillation and is uncommon in a structurally normal heart.³ The atrial flutter rate is usually 300 beats/min, but can be slower (240-440 beats/min) especially in patients on antiarrhythmic therapy. The ventricular rate which is determined by the AV conduction ratio is usually a 2:1 with the resultant ventricular rate of approximately 150 beats/min (Figure 23-5). Higher degrees of AV block and variable HRs can be seen in patients due to underlying cardiac disease or AV nodal conduction disease and those on antiarrhythmic agents. Atrial flutter with 1:1 AV conduction and ventricular rates as high as 300 beats/min is poorly tolerated and can be seen in cases of sympathetic stimulation or in the presence of an accessory pathway. Flutter waves are best identified in the inferior leads and demonstrate a typical “sawtooth pattern” with

FIGURE 23–5 A 12-lead electrocardiogram showing atrial flutter with variable atrioventricular block with a ventricular rate of 128 beats/min. Note the presence of “saw tooth” waves in the inferior leads indicative of a typical or counterclockwise reentry circuit.

absence of an isoelectric baseline. The flutter waves are negative in the inferior leads if the reentry circuit is anticlockwise and positive if the reentry circuit is clockwise (uncommon variant). The rhythm while usually regularly can be irregular in the presence of variable AV block.

In patients with acute hemodynamic collapse or severe symptoms due to atrial flutter, DC synchronized cardioversion is indicated. Atrial flutter can be converted using relatively small amounts of electrical energy, usually less than 50 joules. Alternatively, if pharmacologic conversion is deemed necessary, ibutilide is considered the drug of choice, but carries a risk of QT prolongation and torsade de pointes mandating close monitoring with aggressive repletion of magnesium and potassium.

Atrial flutter also can be converted to sinus rhythm with overdrive pacing. Atrial flutter is amenable to radiofrequency ablation, with success rates approaching those for other supraventricular tachycardias and provides effective long-term treatment. AV nodal blockers can be used to slow down the ventricular rate in hemodynamically stable patients; however, rate control is more difficult to achieve in

atrial flutter. Digoxin can be considered for ventricular rate control in patients with congestive heart failure or hypotension.

Regardless of whether a rate or rhythm control method is employed, anticoagulation strategies to prevent systemic embolization must be considered in patients with atrial flutter. The risk assessment and therapeutic recommendations follow the same principal as atrial fibrillation.

ATRIAL FIBRILLATION

Atrial fibrillation is the most common dysrhythmia in the general population and is highly prevalent in the critically ill.⁴ Affected patients are at increased risk of cardiovascular morbidity and mortality.⁵ It is characterized by disorganized atrial electrical activity probably owing to multiple reentry circuits within the atria that results in loss of atrial contraction and irregular and often times rapid ventricular rates. It is easily recognized on the surface EKG as a narrow complex, irregularly irregular, supraventricular rhythm with a loss of clear P waves, and/or the presence of fibrillatory waves ([Figure 23–6](#)).

FIGURE 23–6 A 12-lead electrocardiogram showing atrial fibrillation with a rapid ventricular rate of 179 beats/min. Note the absence of clear P waves and an irregularly irregular rhythm.

This feature distinguishes atrial fibrillation from the other organized atrial arrhythmias.

Atrial fibrillation increases with age and is greater in men compared to women. Most forms of structural heart disease are associated with atrial fibrillation; most commonly hypertensive heart disease, underlying coronary artery disease, and rheumatic heart disease. Other cardiopulmonary and systemic diseases including obstructive sleep apnea, diabetes, obesity, metabolic syndrome, hyperthyroidism, chronic kidney disease, and postsurgical states have also been associated with atrial fibrillation. Premature atrial contractions are a trigger for atrial fibrillation. In addition, transition between atrial fibrillation and other supraventricular arrhythmias, especially typical atrial flutter is noted frequently. Initial diagnostic workup should include a careful history and physical examination (focusing on the duration and symptoms associated with the arrhythmia, identifiable exacerbating factors, and underlying cardiopulmonary or systemic disease processes), pertinent labs (including serum electrolytes and thyroid function tests), and specific cardiovascular workup (transthoracic and in select cases transesophageal echocardiogram).

As with other arrhythmias, initial assessment should focus on hemodynamic stability as well as identification and correction of underlying causes. Therapeutic considerations in atrial fibrillation include the three nonmutually exclusive strategies of rate control, rhythm control, and systemic thromboembolism prevention.^{6–9} Recent clinical trials have demonstrated similar outcomes with rate and rhythm control strategies; however, there may be crossover from one to another strategy due to the natural history of the disease, failure of the initial strategy, or patient preference.¹⁰

Rhythm control strategies include synchronized DC cardioversion, pharmacologic conversion using antiarrhythmic drugs, radiofrequency catheter ablation, and/or surgical procedures (eg, Maze procedure). Urgent cardioversion should be considered for hemodynamically unstable, severely symptomatic patients, and in the presence of underlying preexcitation. Indications have been summarized in [Table 23–1](#). Several antiarrhythmic agents can be used for pharmacologic rhythm control; however, careful attention should be paid to appropriate patient selection and the side-effect profile and proarrhythmic potential of these medications.

TABLE 23–1 Indications for urgent cardioversion in atrial fibrillation.

Hypotension/shock
Acute or ongoing myocardial ischemia
Congestive heart failure and/or acute pulmonary edema
Underlying preexcitation with rapid ventricular rates and/or hemodynamic instability

For patients without evidence of structural heart disease or coronary artery disease, class Ic agents like propafenone or flecainide can be considered. Patients should be monitored for QRS widening after initiation of these drugs. For patients with evidence of structural heart disease, amiodarone, sotalol, dronedarone, ibutilide, and dofetilide are the most commonly recommended antiarrhythmic agents. In patients with coronary artery disease without left ventricular dysfunction sotalol, dofetilide, amiodarone, and dronedarone are reasonable choices. In patients with left ventricular (LV) dysfunction and clinical heart failure, antiarrhythmic choices include amiodarone and dofetilide. QT interval should be monitored with class III antiarrhythmics. Sotalol and dofetilide are both affected by renal insufficiency and may require dose adjustment or discontinuation. Amiodarone requires dose adjustment in hepatic dysfunction and has significant systemic side effects with a propensity to cause pulmonary, cardiac, thyroid, ocular, dermatologic, hepatic, and gastrointestinal side effects which must be carefully considered prior to initiating treatment.

Most patients will require slowing of the ventricular rate associated with atrial fibrillation. Pharmacologic approach includes AV nodal blocking agents, namely, nondihydropyridine calcium channel blockers and beta-blockers. In patients with congestive heart failure or hypotension, digoxin can be considered. In select patients, combination therapy may be necessary, but excessive AV nodal blockade should be avoided. A-V node ablation with ventricular pacing is an alternative nonpharmacologic rate control approach, but rarely an acute treatment.

An important aspect of atrial fibrillation management includes prevention of thromboembolism. Patients with atrial fibrillation are at risk for

systemic embolization and stroke. The noncontracting atria are a potential nidus for thrombus formation, which usually occurs in the left atrium and left atrial appendage. Multivariate risk models are available to aid in estimation of the thromboembolic risk in patients with nonvalvular atrial fibrillation so that appropriate antithrombotic prevention strategies can be recommended. The most commonly used and well validated being the CHADS2 point score (Congestive heart failure, Hypertension, Age ≥ 75 years, Diabetes mellitus, and prior Stroke or transient ischemic attack) index.¹¹ Patients without any of these risk factors have a CHADS2 score of 0 are at low risk of thromboembolic events and do not require long-term antithrombotic therapy. Patients with a score of 1 are at intermediate risk and can be treated with oral anticoagulant therapy or aspirin. Patients with a score of 2 or higher on the CHADS2 index are considered to be at high risk for thromboembolic events and anticoagulant therapy is recommended unless there are contraindications. Choices include the conventionally used vitamin K antagonist warfarin or newer direct thrombin inhibitor such as dabigatran and factor Xa inhibitors, such as rivaroxaban or apixaban. The new agents should not be used in the presence of severe renal insufficiency, prosthetic heart valves, and in cases of valvular atrial fibrillation. Initial therapy in critically ill patients may be unfractionated or fractionated heparin in the acute period of care prior to conversion to one of these agents.

Hemodynamically stable patients with atrial fibrillation of unknown duration or those with atrial fibrillation for more than 48 hours should be therapeutically anticoagulated for 3 to 4 weeks before elective conversion is attempted. Alternatively, the patient can be started on anticoagulation and if a transesophageal echocardiogram rules out existing thrombi, elective cardioversion can be performed safely. Anticoagulation should be continued for 4 weeks after cardioversion.

The differences in the pathophysiology and management of patients that present with atrial fibrillation with an underlying accessory pathway are noteworthy. A rapid ventricular rate (usually greater than 200 beats/min) and evidence of preexcitation are clues to this diagnosis. For hemodynamically unstable patients urgent cardioversion should

be considered. AV nodal blockers should be avoided as they can promote conduction down the accessory pathway resulting in rapid ventricular rates and ventricular fibrillation. Digoxin and adenosine should also be avoided. Antiarrhythmic choices for rhythm control include procainamide, amiodarone, ibutilide, flecainide, and propafenone. Transvenous radiofrequency catheter ablation of bypass tracts obviates the need for long-term pharmacologic therapy and has largely replaced surgical ablation due to its high curative success rates in patients with bypass tracts.

VENTRICULAR TACHYCARDIAS

Ventricular tachycardia is defined as 3 or more consecutive VPCs at a rate of at least 100 beats/min, but is not considered sustained unless it persists for at least 30 seconds. It is usually monomorphic and is a reentry arrhythmia (Figure 1b). It is easily differentiated from an accelerated idioventricular rhythm (AIVR) which is a wide complex rhythm at 40 to 60 beats/min that is usually due to increased automaticity or is an escape rhythm due to bradycardia (Figure 1a). AIVR is usually transient and does not require treatment other than addressing the underlying cause. Rapid ventricular tachyarrhythmias, especially in patients with structural heart disease and ischemia are more likely to cause hemodynamic compromise and to degenerate into ventricular fibrillation. Ventricular fibrillation requires emergency defibrillation as per Advanced Cardiac Life Support recommendations and protocols.¹² Unstable patients such as those with hypotension, exacerbation of heart failure, obtundation, or unstable ischemic chest pain who develop ventricular tachycardia should be treated by emergency electrical cardioversion starting with 100 to 200 J and increasing up to 360 J to restore sinus rhythm. Pharmacologic treatment may be needed in addition, but can be used alone in patients who have sustained ventricular tachycardia and remain hemodynamically stable.¹³ These drugs need to be used carefully as many antiarrhythmic agents have significant proarrhythmic side effects and potassium and magnesium replacement should be given. Initial treatment with amiodarone is recommended as a first-line agent. IV infusion of 150 mg of amiodarone over 10 minutes

can be given. The full loading dose of amiodarone is given over 24 hours at 1 mg/min over the first 6 hours followed by 0.5 mg/min over the next 18 hours for a total of 1050 mg. Subsequent maintenance doses can be given orally or intravenously as tolerated. Beta-blockers and procainamide are alternatives. Lidocaine can be used in patients with acute cardiac syndromes and other drugs, such as sotalol, propafenone, and flecainide are second-line agents due to their high incidence of proarrhythmic effects. Overdrive pacing can be considered in patients with sustained ventricular arrhythmias that are refractory to antiarrhythmic agents.

Torsade de pointes and other forms of polymorphic tachycardia are rapid ventricular rhythms associated with hemodynamic instability and a predisposition to degenerate into ventricular fibrillation.¹⁴ Polymorphic ventricular tachycardia is commonly associated with ischemia and is likely to require cardioversion and consideration of rapid myocardial revascularization. In Torsades de pointes, the morphology of the QRS complexes varies in a pattern of twisting points and changes of axis associated with marked QT prolongation of greater than 500 ms (Figure 23–7). It can be caused by electrolyte abnormalities, ischemia, and proarrhythmic effects of antiarrhythmic agents such as flecainide, propafenone, quinidine, and sotalol and by other agents and drug interactions that increase the QT interval. Common causative agents include antibiotics, antihistamines, antifungal agents, tricyclic antidepressants, and phenothiazines. Although less common than acquired QT prolongation are patients with congenital QT prolongation (Romano–Ward Syndrome and Lange–Jervell–Neilson Syndrome) who are at risk for polymorphic ventricular tachycardia. Treatment is directed to reversing the inciting causes of the arrhythmia and to shortening the QT interval. IV magnesium should be given and potassium level repleted to 4.5 to 5 mmol/L. The stimulating factors should be removed or corrected as much as possible. The absolute QT interval should be shortened by increasing the HR with atropine, isoproterenol infusion, or overdrive pacing. As with any unstable patient with ventricular tachycardia, electrical cardioversion may be needed.

Other less common causes of ventricular tachycardia/ventricular fibrillation can sometimes be

FIGURE 23–7 A 12-lead electrocardiogram of Torsade de pointes. Unstable rapid polymorphic ventricular tachycardia demonstrating the shifting heights and constantly changing axes of the ventricular complexes.

found in patients in the ICU and need to be recognized. Patients with Brugada syndrome may be predisposed to polymorphic ventricular tachycardia and ventricular fibrillation. EKGs show varying degrees of right bundle branch block and right precordial ST elevations, which may not always be present at baseline, but can be induced during periods of stress and by medications. These patients with life-threatening arrhythmias will require automatic implantable cardioverter defibrillator (AICD) implantation in addition to the acute treatment described earlier. Another variant of stress or exercise-induced ventricular tachycardia usually arises from the right ventricular outflow tract and less commonly from a site in the left ventricular outflow tract. This is usually a more benign arrhythmia that presents with paroxysmal ventricular tachycardia with a LBBB pattern that responds to adenosine or beta-blockers. This rhythm can eventually be treated with radio-frequency catheter ablation of the initiating site in the outflow tract although long-term treatment with beta-blockers can be effective.

All ventricular arrhythmias can be markers for poorer long-term prognosis and sudden death in

patients associated with left ventricular dysfunction and ischemic heart disease.¹³ Patients with nonsustained ventricular tachycardias and ischemic heart disease in ICU settings, especially those with acute cardiac syndromes should be given beta-blockers to control HR, blood pressure, and rhythm disturbances in addition to electrolyte replacement and control of other stimulatory factors such as anemia, pain, and fever. Long-term treatment strategies for these patients may include AICDs and biventricular pacing especially if there is persistent left ventricular dysfunction with no reversible inciting factors for the ventricular arrhythmia. While these devices have improved outcome in some patients, they are rarely indicated acutely in the treatment of patients in the ICU. Patients should eventually be referred for cardiac evaluation to see if they qualify for device implantation under the current guidelines.^{13,15,16} Patients with ventricular arrhythmias and structural heart disease, such as hypertrophic cardiomyopathies and congenital syndromes, such as Brugada syndrome may benefit from earlier electrophysiologic referral for secondary prevention of ventricular arrhythmias and sudden death.

Acute Cardiac Ischemia

Matthew I. Tomey, MD and Umesh K. Gidwani, MD

KEY POINTS

- 1 Any acute imbalance between myocardial oxygen supply and demand may result in a syndrome of acute cardiac ischemia. Potential mechanisms include acute changes in coronary anatomy, as in plaque rupture and thrombosis, and acute changes in physiology as in sepsis and hemorrhage.
- 2 Acute cardiac ischemia progresses in a typical cascade through perfusion abnormality, metabolic disturbances, diastolic and systolic dysfunction, electrocardiographic changes, symptoms, and ultimately myocardial necrosis, with associated rise in serum biomarkers of myocardial infarction. Therapy to interrupt this cascade is time sensitive in order to prevent irreversible loss of myocytes.
- 3 Key elements of initial evaluation of suspected acute cardiac ischemia include a chest pain history, focused examination to exclude alternate diagnoses and assess hemodynamic stability, and a 12-lead electrocardiogram to identify ST-segment elevations. Serum biomarkers of myocardial infarction including troponin creatine kinase and its MB fraction should be measured for diagnostic and prognostic purposes, but should not delay urgent management.
- 4 Directed therapy for acute cardiac ischemia should target the suspected mechanism of ischemia. When plaque rupture, thrombosis, and acute obstruction to coronary blood flow are suspected, appropriate treatment includes dual antiplatelet therapy with aspirin and an adenosine diphosphate receptor antagonist, anticoagulation, statin therapy, and consideration of reperfusion therapy. When stable coronary anatomy and an acute change in physiology are suspected, treatment should prioritize correction of the offending physiologic derangements.
- 5 Acute cardiac ischemia with ST-segment elevations is a medical emergency requiring immediate cardiology consultation and consideration of reperfusion therapy, including potential primary percutaneous coronary intervention or fibrinolytic therapy.

INTRODUCTION

Acute cardiac ischemia is defined by new or worsening imbalance between myocardial oxygen supply and demand, most commonly in the setting of coronary artery disease. Despite improvements in

medical therapy, the burden of coronary artery disease remains high, affecting over 15 million United States adults.¹ Acute cardiac ischemia describes a physiologic disturbance underlying a spectrum of disorders encountered in critical care, from so-called

“demand ischemia” in the setting of an acute physiologic insult and stable ischemic heart disease, to acute coronary syndromes (ACS), including unstable angina (UA), non-ST segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI).

Whereas certain physiologic principles of acute cardiac ischemia are common across this spectrum, providing the basis for understanding its natural history and therapy, appropriate management varies importantly with the mechanism of disease. As such, the ability to both identify and discriminate acute cardiac ischemia is fundamental to timely selection and implementation of appropriate therapy. In this chapter, we aim to provide a practical, intuitive review of the spectrum of acute cardiac ischemia for the critical care provider.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Cardiac ischemia results from an imbalance between myocardial oxygen supply and demand. Acute disturbances in supply, demand, or both can precipitate a syndrome of acute cardiac ischemia. Major determinants of myocardial oxygen supply and demand are presented in [Table 24–1](#).

Determinants of Myocardial Oxygen Supply

Oxygen uptake by tissue is governed by oxygen delivery and oxygen extraction. Because myocardial

oxygen extraction is near-maximal, at 70% to 80%, variation in myocardial oxygen supply is primarily driven by delivery of oxygen. Delivery of oxygen is directly related to cardiac output, or blood flow, and the content of oxygen in arterial blood (**Equation 24–1**). Cardiac output is the product of heart rate and left ventricular stroke volume (**Equation 24–2**). Arterial oxygen content is determined by the hemoglobin concentration, arterial oxygen saturation, and partial pressure of oxygen in arterial blood (**Equation 24–3**).

$DO_2 \propto CO \times CaO_2$ (24–1)

$CO = HR \times SV$ (24–2)

$CaO_2 = (Hb \times 1.39 \times SaO_2) + (PaO_2 \times 0.003)$ (24–3)

Oxygenated blood is delivered to the myocardium via branches of the coronary arteries. Normal coronary anatomy consists of a right coronary artery (RCA) arising from the right sinus of Valsalva and a left main coronary artery arising from the left sinus of Valsalva, which in turn bifurcates into the left anterior descending and left circumflex arteries ([Figure 24–1](#)). The coronary arteries and their branches develop as anatomical “end arteries,” providing all or most of the blood supply to specific areas of subtended myocardium. Typically, the RCA supplies blood to the right ventricle and inferior wall of the left ventricle, the left circumflex supplies blood to the lateral and inferior walls of the left ventricle, and the left anterior descending supplies blood to the anterior wall of the left ventricle. Anatomic variations are common. Furthermore, collateral circulation can develop over time as an adaptation to chronic ischemia.

Myocardial blood flow is driven by the pressure gradient from the aortic root to the myocardial capillaries, the coronary perfusion pressure, and inversely related to coronary arterial resistance.

Coronary perfusion pressure is equal to the difference between aortic diastolic pressure and left ventricular end-diastolic pressure. Blood flow to the left ventricular myocardium occurs primarily during diastole, when aortic pressure exceeds left ventricular

TABLE 24–1 Key factors influencing myocardial oxygen supply and demand.

Supply	Demand
Cardiac output	Contractility
Hemoglobin concentration and oxygen saturation	Systolic blood pressure/afterload
Diastolic blood pressure	Preload
Left ventricular end-diastolic pressure	Heart rate
Coronary vasomotor tone	
Heart rate

pressure due to closure of the aortic valve. During systole, in contrast, left ventricular pressure equals or exceeds (in the case of any left ventricular out-flow tract obstruction) aortic pressure. Accordingly, decreases in aortic diastolic pressure and increases

in left ventricular end-diastolic pressure will tend to decrease myocardial blood flow. In a given coronary artery, anatomic obstruction (such as by atherosclerotic plaque, thrombus or embolus) may cause limitation or complete interruption of blood flow. Clinically important obstruction may occur at the macrovascular or microvascular level. Whereas the duration of systole is fairly fixed, the duration of diastole is variable and dependent on heart rate. As such, myocardial blood flow is also heart rate dependent; other things being equal, increases in heart rate decrease diastolic filling time and tend to reduce myocardial blood flow.

Resistance to coronary arterial blood flow is dynamic. A complex array of paracrine, endocrine, neural, and mechanical factors mediate local and global increases or decreases in coronary arterial resistance, in large part through modulation of coronary vasomotor tone. The capacity for localized changes in coronary vasomotor tone permits heterogeneity in coronary arterial resistance and local adaptation to physiologic circumstances, including ischemia. Decreases in local or global coronary arterial resistance tend to increase myocardial blood flow and, in turn, myocardial oxygen delivery.

DETERMINANTS OF MYOCARDIAL OXYGEN DEMAND

Oxygen is used by cells, including cardiac myocytes, as the ultimate electron acceptor in a series of redox reactions that culminate in generation of adenosine triphosphate (ATP) by oxidative phosphorylation. ATP is required to power energy-dependent cellular processes; in cardiac myocytes, this includes regulation of membrane potential, regulation of sarcoplasmic reticulum calcium concentration, and both cross-bridge formation and dissociation of actin and myosin (required for contraction and relaxation, respectively). Demand for ATP and, in turn, demand for oxygen, relates to the magnitude of this cellular work.

Accordingly, beyond myocardial basal energy expenditure, myocardial oxygen demand is driven by the work of each cardiac cycle and the number of cardiac cycles per minute (the heart rate). The work

of a given cardiac cycle relates closely to wall stress—the force applied to a unit area of myocardium. As expressed by the Law of Laplace (**Equation 24–4**), wall stress is directly proportional to pressure and radius and inversely proportional to wall thickness. As such, wall stress and, in turn, myocardial oxygen demand will tend to increase in association with increases in contractility and systolic blood pressure (increasing left ventricular systolic pressure), obstruction to left ventricular outflow (increasing left ventricular systolic pressure), volume overload (increasing left ventricular radius and end-diastolic pressure), and decreased compliance (increasing left ventricular end-diastolic pressure).

$$\text{Wall stress} = \frac{P \times r}{2h} \quad (24-4)$$

The Ischemic Cascade

Following onset of acute cardiac ischemia, a typical sequence of events ensues, referred to as the ischemic cascade (**Figure 24–2**). The earliest detectable change is a local abnormality in myocardial perfusion. This is followed in course by tissue-level metabolic disturbances, regional diastolic dysfunction, regional systolic dysfunction, electrocardiographic changes, symptoms, and finally irreversible cellular injury progressing to cell death (myocardial infarction).

The pace of this cascade depends on the severity of myocardial ischemia. With acute thrombotic total occlusion of an epicardial coronary artery, contractile changes are evident within 1 to 2 minutes; within 10 minutes, alterations in membrane potential

FIGURE 24–2 The ischemic cascade.

increase predisposition to malignant ventricular arrhythmias; by 20 minutes, cellular injury becomes irreversible, beginning the process of myocardial infarction.² This rapid progression to risk of life-threatening arrhythmia and irreversible myocardial injury underscores the urgency of evaluation and management of suspected acute cardiac ischemia.

Myofibrillar changes are followed within hours by acute inflammation and coagulation necrosis, which proceeds over several days, followed by removal of dead myocytes by infiltrating macrophages. During this phase of phagocytosis, cardiac tissue is particularly friable and at risk of rupture. After 1 week, granulation tissue begins to form and mature, with progressive removal of cellular tissue and deposition of collagen. The process of scarring completes over 2 months. In parallel, the healing ventricle undergoes a process of remodeling, including changes in ventricular geometry and size. Although an increase in left ventricular end-diastolic volume allows hemodynamic compensation by maintaining stroke volume despite a decrease in systolic function, this remodeling proves maladaptive, contributing to increased myocardial oxygen demand (as aforementioned), chronic heart failure and mortality. For this reason, therapies to prevent such adverse cardiac remodeling are an important component of management of acute cardiac ischemia, as will be discussed in sections to follow.

CLINICAL PRESENTATION

Onset of acute cardiac ischemia is accompanied by a typical constellation of symptoms, signs, and findings on laboratory and imaging investigation. Although the mechanism and severity of acute cardiac ischemia may vary across the spectrum of responsible disorders, elements of the clinical presentation are conserved, which we review here.

HISTORY

The cardinal symptom of acute cardiac ischemia is chest pain. Chest pain typical of cardiac ischemia (angina pectoris) is characterized by provocation by exertion or emotional upset and alleviation by rest or nitrates. Pain is typically retrosternal in location and may radiate to the jaw, throat, or arms. The quality of

TABLE 24–2 Differential diagnosis of acute chest pain in the intensive care unit.

Diagnosis	Historical Features
Pulmonary embolism	Pleuritic Venous thromboembolism risk factors may be present
Pneumonia	Fever Productive cough
Aortic dissection	Tearing quality Sudden onset Radiation to back
Gastritis/esophageal reflux	May vary with meals or antacids
Esophageal spasm	May improve with nitrates
Pericarditis	Positional Pleuritic
Musculoskeletal	Localized May be elicited with palpation, motion or sometimes respiration

pain may be described as pressure-like or squeezing, and patients may even demonstrate this as a clenched fist in front of the chest (the Levine sign). Accompanying symptoms may include dyspnea, diaphoresis, and nausea. Importantly, the chest discomfort of acute cardiac ischemia may be a typical or absent, notoriously in women and patients with diabetes mellitus as well as postoperative or critically ill patients. A high index of suspicion is therefore mandatory. The angina of acute cardiac ischemia is unstable, being of new onset, occurring with rest or minimal exertion, or worsening in intensity, frequency, or duration (typically longer than 20 minutes).

Features on history may suggest a noncardiac source of chest pain. Pain that is pleuritic, positional, sharp, or reproducible with palpation is less likely to represent acute cardiac ischemia. A differential diagnosis is presented in [Table 24–2](#).

Physical Examination

Abnormalities on physical examination are insufficient to rule in or rule out acute cardiac ischemia. Careful physical diagnosis is nonetheless necessary in the setting of suspected acute cardiac ischemia to

identify signs of alternative diagnoses; to assess disease severity; and to identify systemic precipitants of worsening imbalance in myocardial oxygen supply and demand.

A focused investigation for alternative diagnoses should include simultaneous palpation of the bilateral radial pulses and measurement of bilateral brachial blood pressures to look for discrepancy, as might be seen in acute aortic dissection; palpation of the locus of chest discomfort to elicit tenderness, as would be suggestive of a musculoskeletal origin of pain; and auscultation of the chest and precordium to listen for a friction rub, as might be heard in pleuritis or pericarditis, or adventitious lung sounds, as might be heard in pneumonia. It should be noted that fever, while raising the question of alternate diagnoses, does not exclude acute cardiac ischemia, as indeed fever (along with leukocytosis) may be observed during acute myocardial infarction in conjunction with a robust systemic inflammatory response, with adverse prognostic implications.

When acute cardiac ischemia is the most likely diagnosis, physical examination is useful to identify evidence of acute heart failure, hemodynamic instability, and mechanical complications of ischemia and infarction. Manifestations of acute heart failure may include a third heart sound and signs of decreased cardiac output (such as sinus tachycardia, narrow pulse pressure, hypotension, decreased alertness, cool extremities, and thready pulses) or congestion (such as jugular venous distension, tachypnea, hypoxemia, labored breathing, rales, and frank pink, frothy sputum). A new systolic murmur may represent acute mitral regurgitation, resulting from acute ischemic dysfunction of a papillary muscle or, in the setting of acute myocardial infarction, papillary muscle rupture, or formation of a ventricular septal defect. The clinical triad of hypotension, jugular venous distension, and muffled heart sounds mandates investigation for pericardial tamponade, which may result from ventricular free wall rupture.

Electrocardiogram

The surface 12-lead electrocardiogram is the sine qua non of diagnosis and triage of acute cardiac ischemia, and should be performed within 10 minutes of medical contact. While the electrocardiogram should be approached systematically, including

analysis of the rhythm, rate, axis, intervals, and evidence of chamber enlargement, particular attention is paid to the ST segments, T waves, and presence or absence of pathologic Q waves.

ST-segment elevation is the defining feature of STEMI, and a red flag that emergent action may be required. When caused by acute cardiac ischemia, ST-segment elevation is indicative of severe and often transmural ischemia, most commonly secondary to an acute total obstruction to coronary blood flow. Several conditions may explain ST-segment elevations (Table 24–3). To be diagnostic of STEMI, ST-segment elevations of sufficient magnitude (at least 0.1 mV and higher in leads V2–V3) must be present in at least two contiguous leads. The ST-segment elevations of acute cardiac ischemia are characterized by a territorial distribution; elevations in leads V2–V4; V5–V6, I, aVL; and II, III, aVF reflect ischemia in the anterior, lateral and inferior walls, respectively. Ischemic ST-segment elevations are typically characterized by a convex morphology, in contrast to the concave ST-segment elevations observed in pericarditis and early repolarization.

Clinical syndromes consistent with acute cardiac ischemia with no ST-segment elevations on the surface electrocardiogram are considered non-ST elevation ACS, and comprise UA and NSTEMI. The

acute cardiac ischemia of non-ST elevation ACS is typically nontransmural, but may still be extensive, often associated with multivessel coronary artery disease. ST-segment depressions or T wave inversions may be present, but these findings are not required for the diagnosis of UA or NSTEMI.

Of note, in certain syndromes of myocardial infarction, ST-segment elevations may be absent from the standard electrocardiogram despite presence of acute total occlusion of a coronary artery. True lateral, posterior, and right ventricular myocardial infarctions may be occult on the standard electrocardiogram due to their peripheral locations, requiring special placement of posterior (V7–V9) or right-sided (V3R–V5R) leads to reveal the diagnostic ST-segment elevations. These myocardial infarctions are pathophysiologically indistinguishable from those with overt ST-segment elevations and require the same urgency in management. It is of particular importance to recognize right ventricular infarction when it occurs—occasionally in isolation, but most frequently in conjunction with an inferior wall myocardial infarction due to occlusion of the RCA—as acute ischemia of the right ventricle causes exquisite preload dependence and susceptibility to severe hypotension with nitroglycerin.

Serum Biomarkers

Acute cardiac ischemia associated with myocardial infarction is characterized by a typical rise and fall of serum biomarkers of cardiac injury. The most sensitive and specific of these markers are the MB-fraction of creatine kinase (CK-MB), which tends to peak in the first day and fall over the next two, and troponin I or T, which also peaks in the first day but falls more slowly over several days (Figure 24–3). Less-specific serum markers which also rise and fall with acute myocardial infarction include myoglobin, total creatine kinase, aspartate aminotransferase, and lactate dehydrogenase.

Improvements in the sensitivity of laboratory measurements of serum troponin have not only permitted superior recognition of myocardial injury in the setting of acute cardiac ischemia, but also identification of troponin elevations in the setting of other acute illnesses. This is particularly relevant in the critical care setting. Troponin elevations

FIGURE 24–3 Kinetics of cardiac-specific biomarkers in myocardial infarction. A, myoglobin after MI; B, troponin after MI; C, CK-MB after MI; D, troponin in UA. (Reproduced with permission from Wu AH, Apple FS, Gibler WB, et al: National Academy of Clinical Biochemistry Standards of Laboratory Practice: recommendations for the use of cardiac markers in coronary artery diseases, *Clin Chem* 1999 Jul;45(7):1104-1121.)

can be seen with nonischemic myocardial injury, as in myocarditis, toxic insults, rhabdomyolysis, defibrillator shocks, and cardiac contusion as well as severe systemic illnesses, such as sepsis, stroke, and renal failure.³ In isolation, an elevation in serum troponin is insufficient for diagnosis of acute cardiac ischemia.

Adjunctive Imaging

When laboratory studies, clinical examination, and the electrocardiogram are indeterminate for the diagnosis of cardiac ischemia, adjunctive imaging modalities with increased sensitivity to detect ischemia may be useful. The role of these tools is intuitive in the context of the ischemic cascade (see Figure 24–2). Echocardiography may detect new regional or global abnormalities in systolic or diastolic function as well as potential complications of acute cardiac ischemia, such as new onset mitral regurgitation. The transthoracic echocardiogram is a particularly useful tool in the intensive care unit as it can readily be performed portably at the bedside without requirement for radiation or nephrotoxic contrast media. For patients sufficiently stable to undergo stress testing, vasodilator testing with

myocardial perfusion imaging can be used to identify regional abnormalities in myocardial perfusion.

Coronary angiography, performed either noninvasively via computed tomography or invasively via cardiac catheterization, provides an anatomic depiction of coronary arterial patency. Although a 70% or greater diameter stenosis of the lumen of a coronary artery tends to connote a hemodynamically important obstruction to blood flow, it is important to recognize that angiography, by itself, is not a physiologic test of ischemia. For lesions of uncertain hemodynamic significance in the catheterization laboratory (and soon, the computed tomography suite), fractional flow reserve may be used to verify obstruction.

Universal Definition and Classification of Myocardial Infarction

Acute myocardial infarction is defined by clinical evidence of acute cardiac ischemia and a rise and/or fall in troponin, exceeding the 99th percentile of the normal reference population for a given laboratory.³ Based on the clinical scenario, myocardial infarction may be classified into one of 6 types (1, 2, 3, 4a, 4b, or 5; see Table 24–4).

TABLE 24–4 Universal classification of myocardial infarction.

Type	Description
1	Spontaneous
2	Secondary to an ischemic imbalance
3	Resulting in death when biomarkers are unavailable
4a	Related to percutaneous coronary intervention
4b	Related to stent thrombosis
5	Related to coronary artery bypass grafting

Data from Thygesen K, Alpert JS, Jaffe AS, et al: Third universal definition of myocardial infarction, *J Am Coll Cardiol* 2012 Oct 16; 60(16):1581-1598.

THERAPEUTIC APPROACH

Critical care pathways differ importantly across the spectrum of acute cardiac ischemia. However, the core principle of therapy is shared: to restore balance between myocardial oxygen supply and demand. In this respect, it is fruitful to first undertake a general review of therapies used in the acute management of acute cardiac ischemia (Table 24-5) from a physiologic perspective.

Antithrombotic Therapy

Antithrombotic therapies, including antiplatelet and anticoagulant drugs, are useful in the acute setting when acute cardiac ischemia results from an acute coronary anatomic change (eg, atherosclerotic plaque rupture) associated with a tendency to thrombosis. This is to be contrasted with the scenario of “demand ischemia,” in which coronary anatomy is stable, but an acute physiologic change has occurred resulting in increased myocardial oxygen demand. (Initiation of dual antiplatelet therapy is not the treatment of choice for acute cardiac ischemia secondary to a gastrointestinal hemorrhage!)

Aspirin is the cornerstone of antiplatelet therapy for patients with ACS. Aspirin inhibits platelets via inhibition of cyclooxygenase and, in turn, down regulation of thromboxane A2. In the setting of ACS, aspirin should be administered as soon as possible as a chewable loading dose (162-325 mg) followed by a daily oral maintenance dose of 75 to 100 mg.

TABLE 24–5 Evidence-based pharmacotherapies in the management of ACS.

Therapy	Examples
Aspirin	Aspirin
Platelet P2Y ₁₂ adenosine diphosphate receptor antagonist	Clopidogrel Prasugrel Ticagrelor
Anticoagulation	Unfractionated heparin Enoxaparin Fondaparinux
High-potency statin	Atorvastatin 80 mg Rosuvastatin 40 mg
Beta-adrenergic blockade	Metoprolol
Angiotensin converting enzyme inhibitor or Angiotensin receptor blocker	Lisinopril Valsartan

Dual antiplatelet therapy using aspirin and an antagonist of the platelet adenosine diphosphate receptor has been shown to be superior to aspirin alone in the setting of ACS with or without ST-segment elevation for the prevention of recurrent ischemic events.^{4,5} Originally documented with clopidogrel, this benefit has since been extended to the newer agents prasugrel and ticagrelor.^{6,7} Clopidogrel is administered as an oral loading dose (300 or 600 mg) followed by a daily oral maintenance dose of 75 mg. Prasugrel should only be initiated at the time of coronary angiography, and never in patients with active bleeding or a history of stroke; when used, it is administered as an oral loading dose (30 or 60 mg) followed by a daily oral maintenance dose of 5 or 10 mg. Ticagrelor is administered as an oral loading dose (180 mg) followed by a twice daily oral maintenance dose of 90 mg.

Anticoagulation in the setting of ACS is typically accomplished using an inhibitor of the intrinsic coagulation cascade. Options include unfractionated heparin, administered as an intravenous bolus of 60 units/kg followed by an infusion of 12 units/kg/h, titrated to an activated partial thromboplastin time of 50 to 70 seconds; the low molecular weight heparin enoxaparin, administered as a subcutaneous injection 1 mg/kg twice daily; and fondaparinux.

Glycoprotein IIb/IIIa inhibitors are potent antiplatelet agents still used, in select cases, with cardiology guidance, typically in association with invasive management. Due to an increased risk of bleeding without clear benefit, routine early use of glycoprotein IIb/IIIa inhibitors upstream of invasive angiography is not recommended.⁸

Anti-ischemic Therapy

Multimodal therapies directed at improving balance between myocardial oxygen supply and demand are useful in all forms of acute cardiac ischemia, but must be tailored carefully to an individual patient.

Beta-adrenergic blockers increase myocardial oxygen supply by increasing diastolic filling time and decrease myocardial oxygen demand by reducing heart rate, contractility, and systolic blood pressure. This mechanism explains the utility of uninterrupted beta-adrenergic blockade during the perioperative setting of patients with known coronary artery disease. When feasible, as tolerated by blood pressure, beta-adrenergic blockade should be uptitrated to achieve a resting heart rate of 60 to 80 bpm. When acute cardiac ischemia is accompanied by signs of reduced cardiac output, and in particular tachycardia and hypotension, however, caution should be taken beta-blockade may inhibit the heart's compensatory response to acute systolic dysfunction, precipitating worsening heart failure or cardiogenic shock.

Nitrates, available in transdermal, sublingual, oral, and intravenous formulations, increase myocardial oxygen supply by reducing coronary vasomotor tone and left ventricular end-diastolic pressure and reduce myocardial oxygen demand by decreasing preload and systolic blood pressure. In the setting of ACS, nitrates are useful for the treatment of refractory angina or hypertension, and should be uptitrated as tolerated by blood pressure to achieve chest pain resolution.

Nitrates should be used only with caution in patients with suspected right ventricular infarction or recent use of phosphodiesterase type 5 inhibitors, as this combination may result in hypotension.

Angiotensin converting enzyme inhibitors and angiotensin receptor blockers serve multiple purposes in the setting of ACS, among which is a reduction in myocardial oxygen demand via reduction in systolic blood pressure. As tolerated by blood pressure

and renal function, an agent should be started within 24 to 48 hours of presentation with ACS.

In patients with diminished content of arterial oxygen due to anemia or hypoxemia, red blood cell transfusion or supplemental oxygen may be warranted. Liberal transfusion and superoxygenation, however, are not helpful in the setting of acute cardiac ischemia, and may be harmful.

Analgesic therapy with morphine may indirectly decrease myocardial oxygen demand via reduction in pain and, in turn, heart rate. As morphine may also mask ongoing ischemia, however, it is reserved as a second-line to more direct anti-ischemic therapies. Nonsteroidal anti-inflammatory therapies should be avoided in the setting of ACS.

In select cases of acute cardiac ischemia refractory to medical therapies, mechanical support may be warranted to optimize balance of myocardial oxygen supply and demand. Positive pressure ventilation may reduce myocardial oxygen demand via reduction in work of breathing and preload. Intra-aortic balloon counterpulsation improves myocardial oxygen supply by augmenting coronary perfusion pressure during diastole and reduces myocardial oxygen demand by reducing afterload during systole.

REPERFUSION THERAPY

When acute cardiac ischemia results from acute interruption of blood flow in a coronary artery, reperfusion therapy restores myocardial oxygen supply via restoration of myocardial blood flow. Reperfusion therapy may be accomplished via fibrinolytic therapy, percutaneous coronary intervention, or coronary artery bypass graft surgery. Whereas fibrinolytic therapy is appropriate only for STEMI, percutaneous coronary intervention or bypass grafting may be used in cases of ACS with or without ST-segment elevation.

STATINS

While not strictly an anti-ischemic therapy, inhibitors of 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase (statins) are a fundamental component of management of ACS. Through not only lipid lowering, but also pleiotropic effects, statins stabilize atherosclerotic plaque and reduce risk of recurrent ischemic events in patients with ACS. As soon as

possible upon diagnosis of ACS, in the absence of contraindications, patients should be treated with a high-potency statin, examples of which include atorvastatin 80 mg and rosuvastatin 40 mg.

SPECIFIC CLINICAL SYNDROMES

In patients with suspected acute cardiac ischemia, prompt evaluation and triage is mandatory to permit assignment to syndrome-specific critical care

pathways (Figure 24–4). For detailed, up-to-date discussion of management considerations particular to UA/NSTEMI and STEMI, readers are encouraged to refer directly to current American College of Cardiology/American Heart Association guidelines.^{9,10}

Acute Cardiac Ischemia in the Setting of Stable Coronary Artery Disease

Myocardial infarction “type 2” may result from anatomically stable coronary artery disease when physiologic derangements result in an acute imbalance

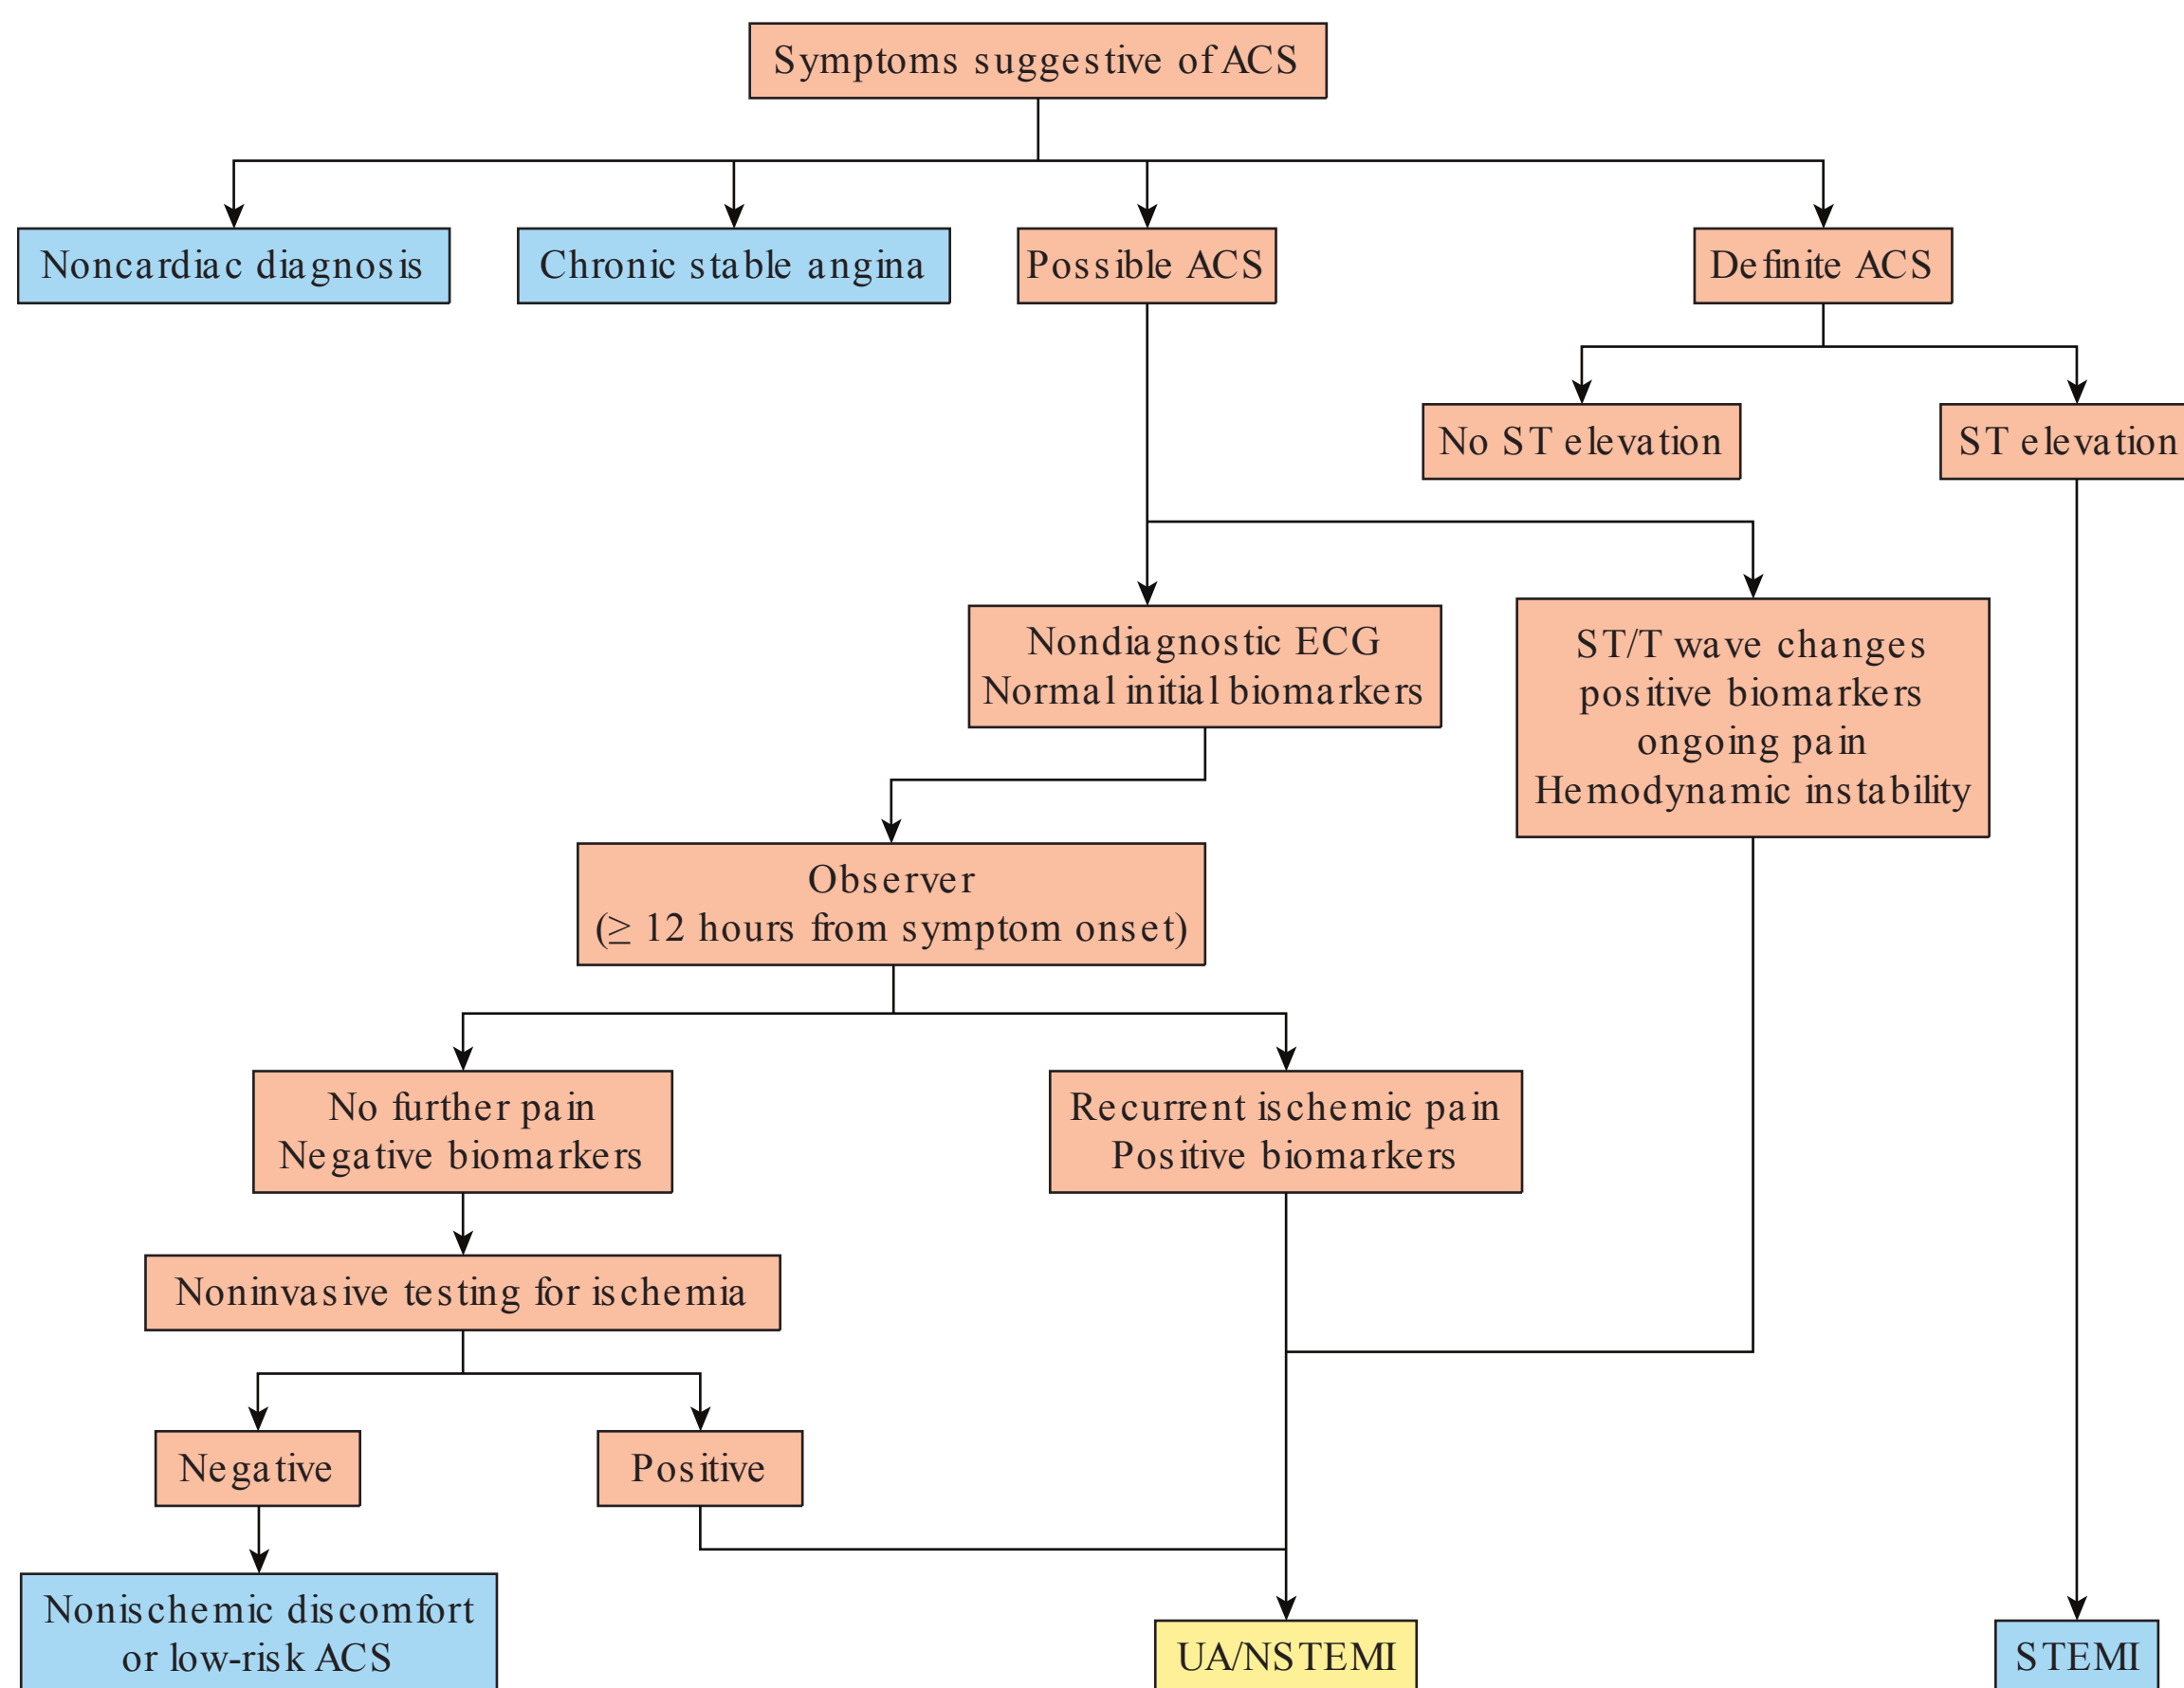

FIGURE 24–4 Diagnostic algorithm for patients with suspected acute cardiac ischemia.

ACS, acute coronary syndrome; ECG, electrocardiogram; NSTEMI, non-ST elevation myocardial infarction; STEMI, ST elevation myocardial infarction; UA, unstable angina. Aortic stenosis	Valvuloplasty Valve replacement

between myocardial oxygen supply and demand and elevation in serum biomarkers of myocardial injury. The key to management of this syndrome is identification and correction of the underlying cause of increased myocardial oxygen demand. Potential etiologies of myocardial infarction type 2 are listed in [Table 24–6](#). In conjunction with this disease-directed approach, supportive measures to mitigate cardiac ischemia include use of anti-ischemic therapies, as discussed earlier.

Of note, demand-mediated acute ischemia in the intensive care unit may not present with classical angina. Symptoms may be atypical or absent (“silent ischemia”). Among patients with known coronary artery disease or coronary risk factors, such silent ischemia is common in the intensive care unit, often unrecognized, and linked with increased morbidity and mortality.¹¹ Reported incidence has varied in series studying different settings and using test modalities with different sensitivities, with ischemic ST changes observed in 11% to 21% and troponin elevations noted in 15% to 38% of patients in published series.^{11–13} Continuous electrocardiographic monitoring using 5 electrodes and 2 leads (typically

II and V5) has a low sensitivity in comparison with a standard 12-lead electrocardiogram and may miss clinically important ischemia.¹³ It is important to recognize, however, that elevation in serum biomarkers of myocardial infarction may occur in the absence of epicardial coronary artery disease, deriving instead from direct effects of catecholamines or other circulating toxins on myocardial cells.

NSTEMI-ACS (UA/NSTEMI)

UA and NSTEMI account for the majority of ACS. When a diagnosis of UA/NSTEMI is suspected, the early priority of management is risk stratification. High-risk cases of UA/NSTEMI benefit from an early invasive management strategy, whereas lower-risk cases may be managed with an initial conservative strategy and provisional invasive angiography. Clinical features indicating high risk include refractory angina, hemodynamic or electrical instability, left ventricular systolic dysfunction, elevated serum biomarkers of cardiac injury, and ST-segment deviation. Global risk scores are also useful for risk stratification; commonly used scores include the TIMI, GRACE, and PURSUIT risk scores.

Regardless of risk profile, all patients diagnosed with UA/NSTEMI should be managed with dual antiplatelet therapy, anticoagulation, a high-potency statin, and optimal anti-ischemic therapy, as discussed earlier. Useful markers of therapeutic efficacy include resolution of chest pain and ST-segment deviations and a downward trend in serum CK-MB. Patients judged to be at high-risk and assigned to an early invasive strategy should undergo invasive angiography to define coronary anatomy and facilitate triage to an appropriate revascularization strategy. Patients deemed to be at low risk may be evaluated first using noninvasive stress testing, with subsequent triage to invasive angiography as warranted.

STEMI

STEMI is a medical emergency. Most commonly resulting from acute thrombotic occlusion of a coronary artery in the setting of coronary atherosclerosis, STEMI reflects severe, acute often transmural cardiac ischemia. “Time is muscle”: reperfusion therapy is time-sensitive to save jeopardized myocardium. As such, management algorithms for

STEMI, including interhospital systems of care, are designed to minimize time to reperfusion therapy, for which primary percutaneous coronary intervention is preferred. Reperfusion therapy is indicated in all eligible patients within 12 hours of symptom onset; between 12 and 24 hours after symptom onset, reperfusion therapy may still be indicated for patients with clinical or electrocardiographic evidence of ongoing ischemia. Current time to reperfusion therapy systems goals include a door-to-needle time of 30 minutes (for fibrinolytic therapy) and a door-to-device time of 90 minutes (for primary percutaneous coronary intervention). In conjunction with expeditious reperfusion therapy, patients diagnosed with STEMI should receive dual antiplatelet therapy, anticoagulation, a high-potency statin, and optimal anti-ischemic therapy, as discussed above. In a limited proportion of cases, patients ineligible for reperfusion therapy will be managed with these medical therapies alone.

Complications of STEMI are of particular concern, and become the focus of critical care following reperfusion therapy. These may be grouped in terms of ischemic, electrical, and mechanical complications.

Ischemic complications include reinfarction and, following percutaneous coronary intervention with stent implantation, acute or subacute stent thrombosis. Symptoms and signs may include recurrent ischemic chest discomfort, ST-segment deviations, and a new rise in serum biomarkers of cardiac injury. Management may require intensification of antithrombotic and anti-ischemic therapy and may include repeat invasive angiography.

Electrical complications may include new onset bradyarrhythmias (including conduction blocks) and tachyarrhythmias, and in particular within the first 24 to 48 hours, ventricular tachycardia. Continuous electrocardiographic monitoring is mandatory to permit prompt identification and acute management of dysrhythmia; indeed, facilitation of prompt defibrillation was a primary motivating factor in the creation of coronary care units.

Mechanical complications include pump failure and cardiogenic shock; acute mitral regurgitation; ventricular septal defect formation; and free wall rupture with pericardial tamponade. Clinicians

must maintain a high index of suspicion for these mechanical complications, which may manifest as fulminant clinical deterioration and which, importantly, may present late, 3 to 7 days following myocardial infarction.

In addition to these complications of STEMI itself, attention must be paid to the complications of our therapy. In particular, patients with both STEMI and UA/NSTEMI are exposed to risk of bleeding as a consequence of the acute provision of antiplatelet, anticoagulant, and invasive vascular therapies. Bleeding complications of ACS are important, with adverse prognostic implications. Patients who bleed are at risk for morbidity and mortality related to bleeding itself as well as heightened risk of recurrent ischemic events, which may relate to withholding of antithrombotic therapies or adverse effects of transfusion.

TRANSITION FROM ACUTE CARE TO SECONDARY PREVENTION

While the emphasis of critical care for acute cardiac ischemia is expeditious restoration of balance between myocardial oxygen supply and demand, also of critical importance is the transition from this acute phase to the work of preventing recurrent ischemic events. The critical care provider has a unique chance to “set the ship on course,” seizing the episode of acute cardiac ischemia as an opportunity to educate the patient about therapeutic lifestyle changes (such as smoking cessation), identify and correct modifiable risk factors for coronary artery disease, arrange for cardiac rehabilitation, and emphasize the importance of medication adherence.

Heart Failure Syndromes in the Critical Care Setting

Omar Saeed, MD and James M. Tauras, MD

KEY POINTS

- 1 The incidence of heart failure (HF) is increasing significantly due to the aging population, improved drug, and device therapies for myocardial infarction as well as heart failure.
- 2 Categorizing HF patients based on volume status (“wet/dry”) and perfusion status (“cold/warm”) can guide treatment as well as risk stratify patients.
- 3 Routine use of inotropic agents in HF patients without a definitive low output state and end organ failure is generally not indicated, since these medications can increase myocardial oxygen demand and can promote arrhythmias, and outcomes data from randomized trials and registry data typically demonstrate worse outcomes with inotropic therapy compared to vasodilator therapy.
- 4 Pulmonary artery catheterization is typically reserved for HF patients with respiratory distress or evidence of hypoperfusion in whom intracardiac filling pressures cannot be determined from bedside assessment as well as patient who are doing poorly with empiric treatment based on clinical assessment.
- 4 Mechanical circulatory support (intra-aortic balloon pump, Impella device, tandem heart, and extracorporeal membrane oxygenation) can be extremely effective therapy in select patients.

HEART FAILURE SYNDROME

Heart failure (HF) is a global clinical syndrome which occurs when the metabolic demands of the body are not met by the circulation due to impairment of cardiac structure and function. Patients typically present with symptoms of progressive dyspnea, decreased exercise tolerance, and may or may not have signs of volume overload and congestion. The final diagnosis of HF must be made by a comprehensive clinical assessment and is not determined by a solitary laboratory value or radiological test.¹⁻⁵

HF WITH REDUCED OR PRESERVED LEFT VENTRICULAR EJECTION FRACTION

HF may occur with or without the presence of left ventricular (LV) systolic dysfunction and thus it is widely categorized into 2 separate entities, namely, HF with reduced ejection fraction (HFrEF) and HF with preserved ejection fraction (HFpEF). Though different investigators and societies have used different definition of HFrEF and HFpEF, the current

American College of Cardiology Foundation/American Heart Association (ACCF/AHA) Heart Failure Guidelines define HFrEF as patients with an LV ejection fraction of 40% or lower; these patients often have varying degrees of diastolic dysfunction as well. Oral HF therapies (beta-blockers, angiotensin converting enzyme inhibitors, mineralocorticoid receptor antagonists, hydralazine, and nitrates) have been extensively validated to provide a quality of life and mortality benefit by many randomized-control trials in patients with chronic HFrEF.

HFpEF includes patients with a left ventricular ejection fraction (LVEF) of 50% or higher and such patients may comprise up to 50% of the entire HF population. HFpEF is described by clinical signs of volume overload, preserved or normal LVEF, and diastolic dysfunction, typically demonstrated by Doppler echocardiography or cardiac catheterization. Patients with HFpEF tend to be older women with hypertension, and other prevalent comorbidities in this group include coronary artery disease, obesity, diabetes mellitus, and atrial fibrillation. To date, no oral HF therapies are proven to demonstrate mortality benefit in this heterogeneous category.

HEART FAILURE DEMOGRAPHICS

Acute heart failure (AHF) is the most common cause of hospitalization in patients more than 65 years old. The relative incidence of heart failure in women is lower than that of men, however, due to their longer life expectancy women represent half the cases of heart failure. The incidence of heart failure increases dramatically with population age. Additionally, the incidence of heart failure admissions to US hospitals has been increasing significantly due to the aging population, improved therapies, and survival for acute myocardial infarction as well as improved drug and device therapies for chronic heart failure. Hospitalization is a key prognostic event in patients with heart failure with reduced ejection fraction as it is predictive of a 30% mortality rate in 1 year and a 50% risk of recurrent hospitalization in 6 months.

ASSESSMENT ACUTE HEART FAILURE SYNDROMES

History

Obtaining and performing a thorough history and physical examination are critical in reaching an accurate diagnosis of AHF and determining the cause of acute decompensation. The major elements of history that should be queried included changes in exercise tolerance, increase in baseline body weight, symptoms of ongoing cardiac ischemia, adherence to, and recent changes in heart failure medications, and signs or symptoms of infection. It is well known that signs and symptoms of heart failure (ie, weight gain, development of peripheral edema, dyspnea, and on exertion) can begin days to even weeks prior to hospital admission. Specific historical information can estimate if AHF involves right- or left-sided cardiac failure. Symptoms of left-sided AHF include dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, while symptoms of right-sided failure may include early satiety and leg edema.

Physical Examination

Although patients with AHF often have a reduced cardiac output, hypotension may not be present. According to the ADHERE registry (a national registry of AHF admissions at 263 hospitals in the United States) the majority of patients with AHF present with a systolic blood pressure (SBP) of greater than 140 mm Hg. This maintenance of blood pressure is due to a catecholamine-mediated increase in systemic vascular resistance. Narrow pulse pressure may be a marker of severe LV dysfunction and tachycardia may be present as a compensatory response or due to ongoing cardiac ischemia. The level of the jugular venous pulsation (JVP) can be used to estimate the central venous pressure and serves as an important bedside measure of intravascular volume. Cardiac auscultation is critical as it can point toward structural and arrhythmic causes of AHF and signs of congestion can be confirmed by pulmonary examination. It is important to note that patients with chronic HF may not have signs of pulmonary congestion due to compensatory lymphatic drainage. Extremities should be examined for warmth or coolness as an indirect measure of perfusion.

Chest X-Ray and Electrocardiogram

Chest radiography is crucial as it cannot only confirm the presence and severity of pulmonary edema, but may also reveal other characteristics of cardiac disease. The cardiac silhouette should be examined for enlargement, size of the pulmonary artery may indicate elevated pulmonary arterial pressures, increased mediastinum width can point to aortic pathology, and the presence of any cardiovascular implantable electronic devices or prosthetic heart valves would indicate preexisting disease. The electrocardiogram is essential to determine if AHF is related to ischemia and arrhythmia and should be serially monitored in patients admitted with acute coronary syndromes.

Laboratory Analysis

Laboratory data can provide more clues in determining the causes of AHF including anemia, thyroid disease, infection, and biomarkers, such as sodium and brain natriuretic peptides cannot only assist in determining volume status, but may also have prognostic value. Renal function is a sensitive marker of

perfusion and intravascular volume, but it should be used in conjunction with the overall clinical assessment, since a decrease in creatinine clearance may occur from reduced cardiac output from either a drop or rise in intravascular volume, direct renal toxicity, or postrenal obstruction. Liver function test abnormalities may be related to congestive hepatopathy or ischemia from severely reduced cardiac output.

Clinical Assessment

The overall clinical assessment is aimed toward placing patients with AHF into one of 4 categories (Figure 25–1) based on their volume and perfusion status, and determining the acute precipitants of AHF. For patients with evidence of intravascular volume overload described as “wet” (elevated JVP, pulmonary rales, and peripheral edema) decongestive therapies such as diuretics or ultrafiltration can be administered to reduce intracardiac filling pressures and reduce dyspnea. If there are signs of reduced perfusion (such as decreased urine output, worsening renal function, and cool extremities)

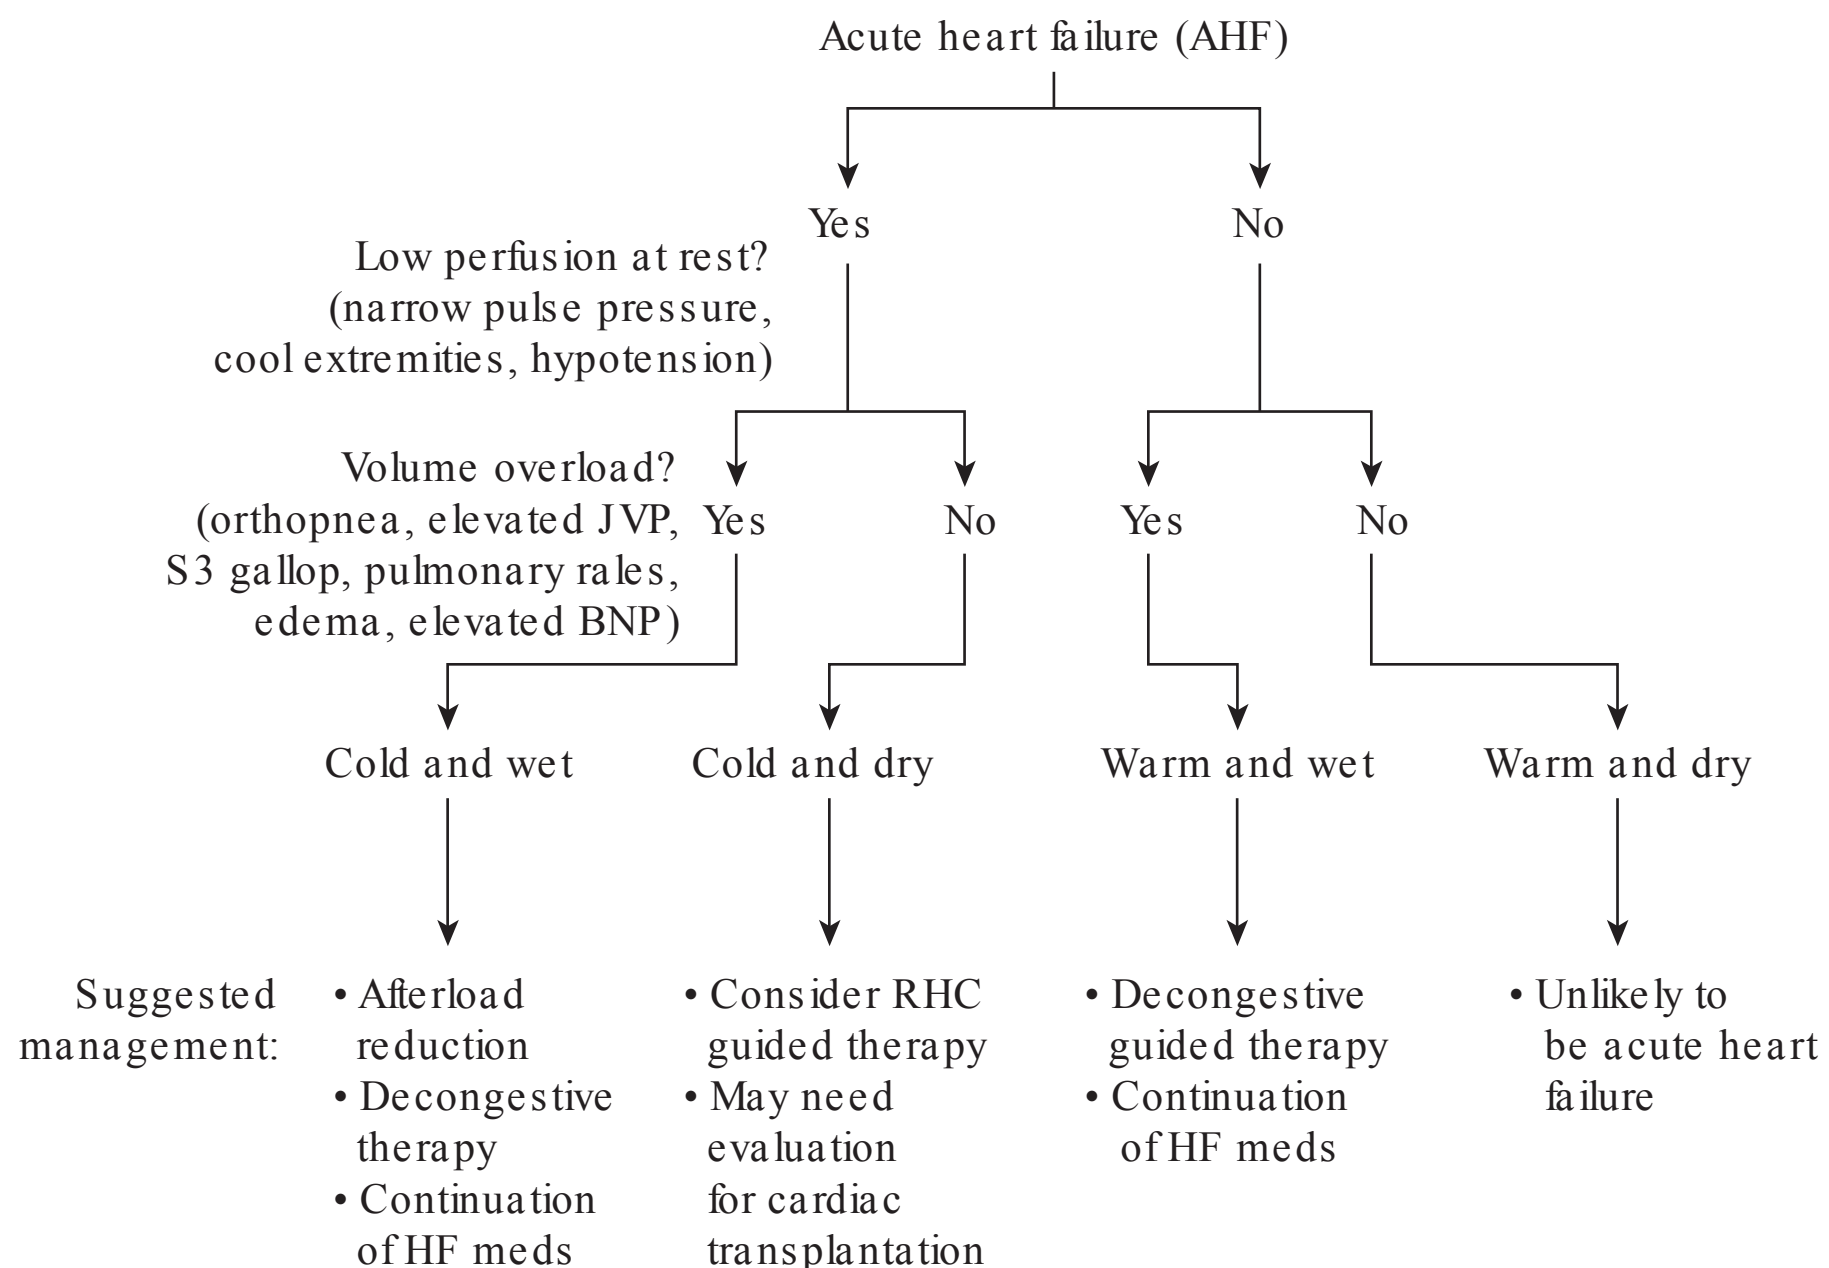

FIGURE 25–1 The overall clinical assessment is aimed toward placing patients with AHF into one of 4 categories.

patients are considered “cool” and in the absence of hypotension, therapies are geared toward augmenting cardiac output by reducing afterload (oftentimes with nitrates and hydralazine). Routine use of inotropic agents without a definitive low output state and end organ failure is generally not indicated, since these medications can increase myocardial oxygen demand and can promote arrhythmias, and outcomes data from randomized trials and registry data typically demonstrate worse outcomes with inotropic therapy compared to vasodilator therapy.

RIGHT HEART CATHETERIZATION

The appropriate use of right heart catheterization in patients with AHF is a subject of considerable controversy. The ESCAPE trial, in which AHF patients were randomized to management with a pulmonary artery catheter (PAC) or careful clinical assessment, demonstrated no mortality benefit or decrease in length of hospitalization with PAC; the trial also demonstrated increased adverse events in the PAC arm driven principally by catheter related infections. Based on these results routine use of PAC in stable AHF patients is not recommended. The

2013 ACCF/AHA Heart Failure Guidelines recommend PAC monitoring for patients in respiratory distress or with clinical evidence of impaired perfusion in whom intracardiac filling pressures cannot be determined from clinical assessment, as well as in patients who are failing (ie, still symptomatic, worsening renal function, and hypotensive) initial empiric therapy based on best clinical assessment. Figure 25–2 shows the typical intravascular and intracardiac pressure profiles of common AHF syndromes.

NONINVASIVE TESTING

Echocardiography is indicated to confirm a new diagnosis of AHF and in those with a significant clinical change from baseline. However, there is limited value in obtaining serial echocardiograms without a significant clinical alteration. This noninvasive modality is a cornerstone for diagnosing pathology involving the pericardium, heart valves, ventricular function, cardiac masses, and congenital defects. In cases of valvular pathology, valve area, valvular gradient, and regurgitant severity can be calculated to determine lesion severity, prognosis and drive further clinical management. Echocardiography can also provide

Clinical scenerio	Systemic blood pressure nL: 120/80 mm Hg	Right atrial pressure nL: 2-6 mm Hg	Pulmonary artery pressure nL: 15-25/8–15 mm Hg	Pulmonary capillary wedge pressure nL: 6-12 mm Hg	Cardiac Index nL: 2.5-4 L/min/m ²	Systemic vascular resistance nL: 800-1200 Dynes-s/cm ⁵

supplementary information about intracardiac pressures in specific cardiac chambers to assist in determination of intravascular volume. For example, in a nonintubated patient if the inferior vena cava is noted to be dilated (> 2 cm) and not collapsing with respiration, the CVP is generally elevated beyond 10 mm Hg. Moreover, pulmonary artery and left sided pressures can be estimated by Doppler echocardiography of tricuspid regurgitation (TR) and mitral inflow, respectively. TR velocities greater than 3 m/s may indicate pulmonary hypertension and diastolic mitral inflow E wave velocities greater 0.12 m/s coupled with a prolonged deceleration time are present with elevated left atrial pressure. Diastolic dysfunction can also be graded by echocardiography.

COMMON PRECIPITANTS OF AHF AND THEIR MANAGEMENT

In addition to improving loading conditions, it is paramount to address the underlying cause of AHF. In cases of acute coronary syndrome, cardiac catheterization is usually indicated to define coronary anatomy and determine either a percutaneous or surgical revascularization strategy. Management of regurgitant valvulopathy typically involves reduction of loading conditions, while stenotic lesions may need surgical intervention. Infections can raise metabolic demand to leading to AHF, especially in patients with reduced LV function and should be promptly treated with antibiotics. Another common scenario is uncontrolled hypertension leading to acute LV diastolic dysfunction and pulmonary edema. Intravenous agents, such as nitroprusside or nitroglycerin, can be administered to reduce blood pressure and diuretics can be given to reduce congestive symptoms. If AHF is caused by persistent tachyarrhythmias, that is, tachycardia-induced cardiomyopathy, then cardioversion may be indicated and an electrophysiologic consultation may be sought to determine optimal pharmacologic or ablative strategies for maintaining sinus rhythm. Dietary and pharmacologic nonadherence are common and recurrent causes of AHF in patients with preexisting chronic HF. In such cases, it is critical to educate patients on appropriate dietary modifications and address any psychosocial or financial

TABLE 25–1 Common precipitating causes of Acute Heart Failure.

Dietary and medication nonadherence
Myocardial ischemia
Uncontrolled hypertension

Uncontrolled thyroid disease
Infection
Valvular heart disease
Aortic dissection
Pericardial disease
Chemotherapy
Anemia

problems that may preclude further compliance with HF medications. Please see [Table 25–1](#) for additional precipitants of AHF.

SEPSIS CARDIOMYOPATHY

Myocardial dysfunction can occur in patients with severe sepsis and is characterized by a reduction in ejection fraction and stroke volume. Cardiac output may be reduced or even normal due to a significant reduction in SVR. Cardiovascular dysfunction during sepsis can increase mortality up to 70% to 90%, in comparison to a 20% mortality in patients with sepsis without cardiovascular involvement. Although several biochemical mechanisms, such as upregulation of endothelin-1, higher expression of inducible nitric oxide synthase leading to free radical toxicity, activation of coagulation pathways and monocyte infiltration have been associated with sepsis cardiomyopathy, the precise mechanism of cardiac dysfunction remains elusive. Management rests upon treating the underlying infectious source and supporting the cardiovascular system.

BRAIN NATRIURETIC PEPTIDE

BNP is a biomarker which has had an increasingly important role in the management of acute as well as chronic heart failure. Originally described in porcine brain extract (and hence “brain natriuretic peptide” or BNP), in human biology it is principally

secreted by ventricular myocytes in response to increased ventricular filling pressures and ventricular stretch. The molecule is secreted as an inactive peptide pro-BNP, and is then lysed into the biologically active BNP as well as the biologically inert amino terminal BNP (NT-BNP). The biologically active BNP acts as a balanced veno- and arteriolar vasodilator and also has direct renal effects, which promote natriuresis and diuresis. Both of the cleaved molecules are used in modern chemistry laboratories for BNP levels.

BNP testing was well validated in emergency room settings in the Breathing Not Properly trial, where BNP testing was demonstrated to be useful in establishing the diagnosis of heart failure in the acutely dyspneic patient. Use of BNP in the critical care setting can be more complicated, as in addition to heart failure, there are many cardiac and noncardiac causes of elevated BNP in hospitalized patients, including but not limited to myocarditis, acute coronary syndrome, pulmonary embolism and sepsis (Table 25–2). BNP levels can be falsely low in very obese patients, and are also lower in HFpEF patients compared to HFrEF patients. Additionally, BNP

levels are elevated in those with renal insufficiency compared to those without renal insufficiency. Finally, higher BNP levels are associated with a higher risk of mortality in both acute and chronic heart failure populations.

MEDICATIONS IN ACUTE
HEART FAILURE SYNDROMES

Sodium Nitroprusside

Sodium nitroprusside (SNP) is a potent vasodilator, with balanced action in the arteriolar and venous beds. It has a very short (seconds to minutes) half-life, and produces a dramatic increase in cardiac output, decrease in pulmonary capillary wedge pressure (PCWP), and decrease in mitral regurgitant fraction; this is typically associated with a decrease in mean arterial pressure. The initial dose is 10 mcg/min, with up titration to as high as 350 mcg/min. Since the coronary vasodilatory properties of SNP can promote coronary steal and ischemia in those with significant unrevascularized coronary artery disease, it is not recommended in patient with active ischemia. The metabolism of SNP leads to the release of nitric oxide and cyanide. The symptoms of cyanide toxicity include nausea, abdominal discomfort and dysphoria. As there can be accumulation of cyanide and thiocyanate, caution must be used in patients with renal and hepatic dysfunction.

Nitroglycerin

Nitroglycerin is a potent venodilator, producing rapid decreases in pulmonary congestion, left ventricular end diastolic pressure, LV wall stress, and myocardial oxygen consumption. It has coronary vasodilatory effects as well, making it a good option for patient with ongoing ischemia. Initial intravenous dose is typically 20 mcg/min, with a doubling of the dose every 5 to 15 minutes. Other options for administration include sublingual tablets and sprays as well as topical pastes. Major side effects include hypotension and headache.

Nesiritide

Nesiritide is recombinant B-type natriuretic peptide. It has balanced venous and arteriolar actions,

TABLE 25–2 Causes of elevated natriuretic peptide concentrations.

Cardiac
<ul style="list-style-type: none">• Heart failure, including RV syndromes• Acute coronary syndrome• Heart muscle disease, including LVH• Valvular heart disease• Pericardial disease• Atrial fibrillation• Myocarditis• Cardiac surgery• Cardioversion

and modestly enhances diuresis through direct renal effects. The dose starts at 0.01 mcg/kg/min. Major side effects include headache and hypotension. The ASCEND trial randomized 7141 patients with ADHF to either standard care or nesiritide plus standard of care. Nesiritide demonstrated a modest, statistically nonsignificant improvement in dyspnea; however, there was a higher rate of hypotension in the nesiritide arm of the trial. Importantly, there was no significant change in the rate of death, rehospitalization, or renal function in the nesiritide arm. Though there may be a role for nesiritide in some special populations (ie, diuretic resistant patients), the results of the ASCEND trial do not support the routine use of nesiritide in acute decompensate heart failure.

Milrinone

Milrinone is a positive inotropic agent as well as a vasodilator. It is a phosphodiesterase 3 inhibitor, and its mechanism of action is the inhibition of the breakdown of cyclic adenosine monophosphate (cAMP) in cardiac myocytes, leading to the increase of cAMP-mediated Ca^{++} in the myocyte and hence enhanced myocyte contractility. Similarly, in the vascular smooth muscle, its action is that of increasing cAMP-mediated contractile protein phosphorylation, leading to vascular relaxation. The hemodynamic changes seen with milrinone include an increased cardiac output, decreased SVR, reduced PCWP, and typically a mild decrease in mean arterial pressure. The half-life is approximately 2.4 hours, and it is renally cleared. The largest randomized clinical trial involving milrinone was the OPTIME-CHF trial, which randomized ADHF patients to either milrinone or placebo. Milrinone did not significantly decrease hospitalization length of stay, and did lead to significantly more hypotension and atrial arrhythmias. Use of milrinone is typically reserved patient with evidence of severely reduced cardiac output and end organ damage.

Dobutamine

Dobutamine is a direct beta-1 agonist, which produces positive inotropic and chronotropic effects. The mechanism of action is the binding of the beta-1 receptor, leading to phosphorylation of protein

kinase A, which ultimately leads to an increase in intracellular cAMP and Ca^{++} , leading to enhanced myocardial contractility. There is also a modest alpha and beta-2 effect, which causes mild peripheral vasodilation; in the context of increasing cardiac output, this can cause a variable effect on mean arterial pressure. The major side effects of dobutamine are atrial and ventricular tachyarrhythmias. There is no equivalent large, randomized trial experience with dobutamine in AHF as there is with milrinone, however registry data of AHF patients suggest worse outcomes with dobutamine and hence its use is limited to patients with poor response to diuretics and vasodilators and patients in overt cardiogenic shock.

Dopamine

Dopamine is a naturally occurring compound that plays an important role in many aspects of human body homeostasis, including major roles in neural, cardiovascular, and renal physiology. Dopamine has variable effects on different receptors at different doses; conventionally at low doses (0-2 mcg/kg/min), there is preferential dopamine receptor activation leading to enhanced renal artery vasodilation and enhanced renal perfusion; at 2 to 10 mcg/kg/min, there is enhanced norepinephrine release, leading to enhanced myocardial contractility and mild peripheral vasoconstriction; at doses above 10 mcg/kg/min, there is preferential alpha adrenergic receptor activation causing peripheral vasoconstriction and an increase in mean arterial pressure. In the context of treatment of AHF, dopamine is often used at low or “renal” dose in diuretic resistant patients, or at higher doses in those with frank cardiogenic shock. The limited clinical trial data evaluating the use of “renally dosed” dopamine in heart failure has been mixed. The most recent trial examining this issue (ROSE trial) randomized 360 AHF patients with renal dysfunction to either usual care or renally dosed dopamine (there was an additional low-dose nesiritide arm of the trial); the trial did not demonstrate a significant benefit of dopamine infusion in terms of urine output or change in renal function. Based on prior trial data, renally dosed dopamine is currently given a IIb recommendation by the ACC/AHA Heart Failure guidelines to help enhance urine output and renal perfusion in AHF patients.

Ultrafiltration

Ultrafiltration is a decongestive therapy in which water and small solutes are moved across a semi-permeable membrane to reduce volume overload. Potential benefits of ultrafiltration over intravenous diuretics include more effective removal of sodium, minimal effects on serum electrolytes, decreased neurohormonal activation, and adjustable and potentially very rapid fluid removal rates. The outcomes in prospective heart failure trials in which patients were randomized to ultrafiltration versus diuretic therapy have varied. In the UNLOAD trial, 200 AHF patients were randomized to diuretics versus ultrafiltration; the ultrafiltration arm demonstrated greater fluid loss at 48 hours and a decrease in heart failure admissions in 90 days, with similar safety profile as diuretics. The CARESS-HF trial randomized AHF patients with cardiorenal syndrome to ultrafiltration or diuretics and failed to demonstrate a benefit with ultrafiltration. The cost, need for vascular access, need for nursing training and support are all potential barriers to ultrafiltration in clinical practice. Identifying the most appropriate patients for ultrafiltration therapy is an area of controversy and active clinical research.

Mechanical Circulatory Support

In cases of severe AHF, which is refractory to medical therapy, temporary circulatory support (TCS) can be utilized to improve end organ perfusion. TCS ranges from percutaneously inserted devices, such as intra-aortic balloon pump, tandem heart, and Impella which are able to augment cardiac output by up to 5 L/min. In cases of complete hemodynamic collapse or severe right ventricular failure, venoarterial extracorporeal membrane oxygenation can be placed to completely bypass the cardiopulmonary

circulation. Additional surgically placed TCS includes semidurable continuous-flow ventricular assist devices, such as CentriMag. TCS can serve as a “bridge to recovery” or as a “bridge to decision” in patients who may need implantation of permanent LV assist devices or cardiac transplantation.

Pulmonary Arterial Hypertension in the ICU

Noam Broder, MD and Ronald Zolty, MD, PhD

KEY POINTS

- 1 Pulmonary arterial hypertension is a chronic, progressive disease affecting pulmonary arteries that results in increased pulmonary vascular resistance and pulmonary arterial pressures. As the disease progresses, chronic or acute increases in pulmonary arterial pressures result in right ventricular failure (RVF) which is the most common cause of death in this patient population. RVF is clinically defined as a reduced cardiac output and an increase in right ventricular filling pressure.
- 2 Pulmonary arterial hypertension is diagnosed with a right heart catheterization or Swan–Ganz catheter showing pulmonary arterial mean pressure greater than 25 mm Hg and not by echocardiogram.
- 3 Given the lack of physiologic reserve of patients with pulmonary hypertension, any further physiologic imbalance, such as infection, arrhythmia, or pulmonary embolism can trigger hemodynamic collapse, RVF and result in an ICU admission.
- 4 Patients with pulmonary hypertension are at risk for developing sepsis, pulmonary embolism, and arrhythmia.
- 5 Treatment of patients in the ICU with evidence of right heart failure due to pulmonary hypertension involves supportive care, correcting the underlying cause of the hemodynamic instability and supporting hemodynamic function of the right heart.
- 6 Intubation of patients with pulmonary hypertension and RVF should be avoided.
- 7 Pulmonary vasodilators are used to reduce RV afterload by reducing pulmonary arterial pressures. Medications effective at reducing RV afterload, such as IV Prostanoids, Inhaled Nitric oxide cause improvements in cardiac output and oxygenation.
- 8 Inotropes, such as Dobutamine and Milrinone are used to maintain cardiac output in the presence of cardiogenic shock from right heart failure due to pulmonary hypertension.
- 9 In extreme cases atrial septostomy can be used to reduce RV pressures by shunting blood from the right atrium to left atrium.
- 10 Pressure support medications, such as norepinephrine and vasopressin should be used to maintain systemic blood pressure as well as right coronary artery perfusion of the right ventricle.
- 11 For patients with end stage PAH and RVF refractory to optimized medical treatment, lung transplantation with bridging via extracorporeal life support should be considered.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a chronic, progressive disease affecting small pulmonary arteries that results in increased pulmonary arterial pressures and eventual right ventricular failure (RVF). PAH can be caused by idiopathic or heritable sources, induced by drugs and toxins, has associations with connective tissue disease, HIV infection, portal hypertension, congenital heart disease, schistosomiasis, chronic hemolytic anemia, and can also result from persistent pulmonary hypertension (PHTN) of the newborn.¹ Clinically, PHTN is diagnosed with a right heart catheterization showing pulmonary arterial pressure greater than 25 mm Hg. As the disease progresses, chronic or acute increases in pulmonary arterial pressures result in RVF which is the most common cause of death in this patient population.² RVF is clinically defined as a reduced cardiac output and an increase in RV filling pressure.³ Due to their delicate hemodynamic states and advanced disease, PAH patients in the ICU have mortality rates reported as high as 41%.⁴

Chronic destruction of pulmonary vasculature as well as increases in pulmonary vascular resistance (PVR) and pulmonary arterial pressures cause RVF.⁵ The right ventricle responds to increased pulmonary pressures with compensatory structural changes that compromise the heart's ability to maintain sufficient cardiac output. As such, an understanding of the underlying physiology of PHTN and the right heart is required in order to treat this complex and dangerous disorder in the ICU.

PHYSIOLOGY OF THE RIGHT HEART

The normal structure and function of the right ventricle reflects the low resistance and high compliance and capacitance of the pulmonary vasculature system to which it delivers blood. The thin-walled structure of the right ventricle implies the low resistance of the pulmonary vasculature. Functionally, the right ventricle spends little time in isovolumic contraction or relaxation and as a result is able to generate cardiac output with only a fifth of the energy demanded by the left ventricle (LV).⁶ The right ventricle receives a continuous flow of coronary blood via the RCA

during both systole and diastole.⁶ This blood supply is possible given the thin-walled structure of the RV as well as its relatively small isovolumic activity. Given this physiology adapted specifically for the low resistance pulmonary vasculature, the right ventricle has difficulty responding to the increased resistance of PHTN.⁶ The adaptive changes that the RV undergoes cause structural changes that compromise its ability to maintain cardiac output.

PATHOPHYSIOLOGY OF PAH AND RVF

In order to reduce wall tension caused by the increased afterload of PHTN, hypertrophy of the right ventricle occurs. As a result, coronary flow no longer occurs in diastole despite the increased demand of the hypertrophied right ventricle. Also, the right ventricle spends more time in isovolumic contraction and relaxation in order to overcome increased pulmonary pressures, which results in a reduction of right heart output and greater energy demand.⁶ RV hypertrophy also interferes with the normal motion of the tricuspid valve and together with increased pulmonary pressures results in tricuspid regurgitation.⁶ The growth of the right ventricle also impedes on the function of the LV as the interventricular septum bulges into the LV.⁶ These changes in the right ventricle all contribute to the reduction of cardiac output, which in turn decreases coronary flow to the RV and causes ischemic damage. Finally, this hypertrophy of the right ventricle accompanied by ischemic damage eventually leads to ventricular dilatation and total right heart failure.

CAUSES FOR ICU ADMISSION IN PATIENTS WITH PAH

Given the lack of physiologic reserve of patients with PHTN, any further physiologic imbalance can trigger hemodynamic collapse and result in an ICU admission. The differential diagnosis for patients with PHTN presenting with acute RVF should include the pathologies unique to PHTN discussed later. It is also important to note that advanced treatments for PHTN work to slow progress of the disease, and do not cure the disease. As such, RVF

occurs when the compensatory mechanisms of the RV are overwhelmed by progressive destruction of the pulmonary vasculature even with use of advanced therapies.

Patients with PHTN are at risk for developing sepsis. Patients with low cardiac output may poorly perfuse the bowel, leading to a leaky endothelial barrier that allows bacteria and their toxins to invade, which can result in sepsis.⁷ Prostacyclin, one of the advanced medications for the treatment of PHTN has an immunosuppressive effect.⁸ Additionally, prostacyclin is delivered via an indwelling catheter, which has its own infection risk.⁸ As such, sepsis was found to be the most common identifiable trigger for ICU admission in a study of 46 patients with PAH or inoperable chronic thromboembolic pulmonary hypertension (CTEPH) admitted to the ICU.⁴

The effects of sepsis on the patient with PHTN can be devastating. Sepsis-induced drops in systemic vascular resistance (SVR) can severely compromise patients with reduced cardiac output from PHTN. Furthermore, sepsis has been shown to cause pulmonary vasoconstriction and dysfunction as well as produce cytokines that reduce right heart contractility.^{9,10} Clinically, sepsis was found to be a leading cause of patient mortality in the ICU for patients with PHTN exacerbations.⁴

Iatrogenic causes can also trigger hemodynamic instability leading to an ICU admission in a patient with PHTN. Negative inotropes, such as beta-blockers and calcium channel blockers can depress the contractile ability of the right ventricle and cause an acute decrease in cardiac output. Abrupt cessation of pulmonary vasodilator medications can cause rebound pulmonary vasoconstriction.

PAH also provides a setting for pulmonary emboli to form. Patients with PAH often live sedentary lifestyles due to poor exercise capacity resulting in venous stasis.⁶ Also, pulmonary blood travels slowly through the pulmonary vasculature in PHTN with RVF. A PE with a resulting loss of oxygenation, shunting of blood, and increased pulmonary arterial pressures can severely destabilize the hemodynamics of a patient with PHTN.

As the heart remodels in response to PAH, patients become susceptible to atrial arrhythmias. The remodeling process predisposes patients with PAH to arrhythmias by modulating autonomic

activity and delaying cardiac repolarization.¹¹ Also, ischemic myocardial damage to the RV itself can predispose patients to developing an arrhythmia.¹¹ One study of 231 patients with PAH or CTEPH showed a yearly incidence of 2.8% for new onset supraventricular tachycardia, most commonly atrial fibrillation or flutter.¹² Any loss of the ability of the LA to fill the LV can further reduce CO in addition to the already decreased RV CO. Also, the poorly compliant RV is dependent on the atrial kick of the RA to fill and produce adequate output. As such, onset of arrhythmias was related to clinical deterioration in patients with PHTN and patients with sustained atrial fibrillation had a cumulative mortality rate of 82%, emphasizing the need for conversion to sinus rhythm.¹²

Atrial arrhythmias are challenging to manage in the ICU given the potential negative inotropic effects of beta-blockers and high doses of calcium channel blockers on the right heart. Therefore, rhythm control may be a better management choice than rate control, with amiodarone, cardioversion, or ablation as potential therapies.¹¹

MONITORING IN THE ICU

Careful monitoring of patients with PAH and RVF is necessary given their fragile hemodynamic state.

Hypoxia causes selective pulmonary vessel vasoconstriction as the body attempts to shunt blood to areas of the lung with better oxygenation. However, this process will increase pulmonary arterial pressures and exacerbate PHTN, so pulse oximetry or more invasive methods of monitoring can be valuable tools in the prevention of desaturation.

Troponins should be checked to identify if myocardial infarction was the trigger event for the ongoing PHTN/RVF episode. Trending troponins may also give insight into any ongoing ischemia occurring in the right ventricle due to the PHTN exacerbation.

BNP can be used to confirm dilation of the right ventricle and to trend the function of the right ventricle over time. High admission BNP levels in patients with PAH or inoperable CTEPH were found to be predictive of mortality.⁴

Hemoglobin levels should be monitored and maintained at a level above 10 mg to avoid

compensatory cardiac reaction to anemia as per expert opinion.³

Due to the delicate hemodynamic state of the right heart in PAH, electrolyte disturbances have potential to be very harmful and should be carefully monitored. BUN and creatinine should be followed as measures of kidney function and cardiogenic shock. AST, ALT, and bilirubin should be monitored as markers for liver damage caused by cardiogenic shock. Finally, lactate is a useful marker for ischemia and RV insufficiency.

Echocardiography is a valuable noninvasive monitoring modality used to observe the function and structure of the right ventricle. Echocardiographic signs of right heart failure include RV dilatation and loss of the RV's normal, triangular shape.¹³ Systolic paradoxical motion of the interventricular septum is another sign of RVF as it represents RV systolic overload.¹³ An echocardiogram can also help identify possible causes of the PHTN associated right heart failure exacerbation such as left heart failure, RV ischemia, new valvular abnormalities, or pericardial effusions.¹³ Furthermore, right atrial enlargement, septal displacement, pericardial effusion, and low tricuspid annular plane systolic excursion are echocardiographic signs associated with poor outcomes in patients with chronic right heart failure.¹⁴ However, these associations were identified in chronic right heart failure patients only, and the value of these signs in an acutely ill patient is unclear. For patients with poor transthoracic echocardiographic imaging, a transesophageal echocardiogram is a valuable option, although it is more invasive and, therefore, carries greater risks.

Outcomes of invasive monitoring with pulmonary artery (PA) catheters have not been specifically studied in patients with PAH. Studies of PA catheterization (PAC) in the ICU patient population have shown no mortality benefit and possibly increased mortality with PAC.¹⁵ Furthermore, PAC involves risks including PA rupture and tachyarrhythmia and one study of patients with PHTN receiving nonacute PAC in an expert center showed an incident rate of 1.1% for adverse events.¹⁶ However, information on PA pressures and RVF can be directly obtained from PAC. As such, the decision to monitor patients with RVF/PAH should be made based on individual patient presentation and course, as hemodynamic

information obtained from PAC may give valuable physiologic information only hinted at by indirect biomarkers such as lactate.

ICU MANAGEMENT OF PAH AND RVF

Treatment of patients in the ICU with evidence of right heart failure due to PHTN involves supportive care, correcting the underlying cause of the hemodynamic instability and supporting hemodynamic function of the right heart. Specifically, the goals of supportive cardiac care for PHTN in the ICU focus on maintaining aortic root pressure, systemic blood pressure, and cardiac output as well as reducing pulmonary arterial pressures. If these treatments are ineffective, invasive strategies, such as extracorporeal support and ultimately lung transplantation should be considered. Unfortunately, PAH in the ICU has not been studied extensively, and much of the following information is based on animal studies and studies of other classes of PHTN.

Supportive Care

As discussed earlier, hypoxia can exacerbate elevated pulmonary pressures, so supplemental oxygenation should be used to maintain hemoglobin oxygen saturation to at least 90% to prevent or reverse any hypoxia induced pulmonary vasoconstriction. Also, there is evidence showing the efficacy of oxygen as a selective pulmonary vasodilator in patients with PAH, as treatment with 100% O₂ for 5 minutes in patients undergoing PAC increased cardiac index and reduced PVR.¹⁷

PAH patients should be anticoagulated as they are at high risk for new DVT or PE given their limited mobility and altered pulmonary hemodynamics as discussed above.

Diuresis helps reduce the pressure of fluid overload on a failing right ventricle that is on the far right of the Frank Starling curve. Dialysis should be considered if the patient fails to respond to diuresis. Patients should be followed clinically with regards to fluid management, as over diuresis can reduce cardiac output. As such, input and outputs for the patient should be carefully monitored to ensure diuresis is proceeding appropriately. In the case of

pure diastolic failure of the RV with signs of fluid overload and normal CO, diuresis alone would be the appropriate choice for management.

Intubation of patients with PHTN and RVF should be avoided as sedatives can depress cardiac function and lower SVR and increased transpulmonary pressures can further lower CO. If mechanical ventilation is necessary, pretreatment with catecholamines to avoid a drop in BP may be necessary. Etomidate is a preferred induction agent, as it has relatively fewer effects on vascular tone or cardiac contractility than propofol.⁶ In general, ventilator strategies should avoid high intrathoracic pressures in order to prevent PVR increases or RV preload decrease. Also, ventilation strategies should attempt to prevent compression of pulmonary vasculature by avoiding high lung volumes and should also avoid hypercapnia, hypoxia, and atelectasis, which can increase PVR.¹⁸

Pulmonary Vasodilators

Pulmonary vasodilators are used to reduce RV afterload by reducing pulmonary arterial pressures. Medications effective at reducing RV afterload cause improvements in CO and oxygenation.

Intravenous (IV) prostanoids are short acting pulmonary vasodilators and platelet aggregation inhibitors delivered by continuous IV infusion or implanted perfusion devices. IV prostanoids are potent pulmonary vasodilators and have been used in the treatment of acute RVF in patients after cardiac surgery where they significantly reduced PVR and increased RV function.^{19,20} IV prostanoids should specifically be avoided in patients with PHTN due to left heart failure, as increased volume delivered to the LV can result in pulmonary edema. Hypotension is a significant adverse effect of IV prostanoids and must be watched for as prostanoids are up titrated. Also, IV prostanoids can cause nonselective pulmonary vasodilation resulting in V/Q mismatch and worsening of cardiac and pulmonary function. Other systemic side effects of IV prostanoids include nausea, diarrhea, flushing, and headache.

In order to avoid hypotension V/Q mismatch from IV prostanoids, inhaled prostanoids, which are only approved for chronic treatment of PAH, should be strongly considered in the care of the acutely ill patient. One study of 35 patients with

PAH undergoing right heart catheterization showed greater efficacy of inhaled iloprost versus NO as an inhaled pulmonary vasodilator.²¹ The ultrasonic nebulizer is being used as a delivery device for inhaled prostanoids in the postsurgical setting to treat RVF.⁶

Inhaled NO directly vasodilates the pulmonary vasculature and may be especially useful in patients who cannot tolerate IV prostanoids due to hypotension and v/q mismatch. NO has a short half-life given its rapid deactivation by hemoglobin in pulmonary capillaries. A study of 26 patients with acute RVF admitted to the ICU and treated with inhaled NO showed in half of all patients a significant decrease more than 20% in PVR and pressure.²² Additionally, in a study comparing NO to IV prostanoids in patients with RVF following cardiac surgery, NO was shown to increase CI and reduce PVR with similar efficacy to IV prostanoids.²⁰ However, prolonged use of high concentration inhaled NO can cause methemoglobinemia so cyanosis should be watched for and periodic methemoglobin levels should be drawn. Withdrawal of NO therapy should be carefully monitored as rebound increases in PA pressure can result from abrupt withdrawal.

Although unstudied in an acute setting, IV PDE5 inhibitors, such as Sildenafil may be a possible therapy for patients with PAH and acute RVF. IV sildenafil does have risks of systemic hypotension and V/Q mismatch from nonselective pulmonary vasodilation.

After patients are stabilized with IV or inhaled medications, endothelin receptor blockers and PDE5 antagonists can be added as oral medications for discharge. These oral medications should be bridged carefully over the ICU medication, as abrupt withdrawal of IV prostanoids, inhaled NO or inhaled prostanoids can cause rebound PHTN.

Inotropes

Inotropes are used to maintain cardiac output in the presence of cardiogenic shock from right heart failure due to PHTN.

Dobutamine is a beta-1 receptor agonist that augments cardiac contractility and reduces RV and LV afterload. Animal models of RVF and PHTN had increased CO and RV-PA coupling with little effects on the PA after dobutamine treatment.²³

Dobutamine significantly improved hemodynamics and cardiac function of patients with PH after RV infarction²⁴ as well as increasing RV contractility and decreasing afterload in patients with PH at liver transplantation.²⁵ However, dobutamine is a direct adrenergic agonist and also has an agonistic effect at beta-2 receptors, which can cause vasodilation resulting in hypotension and tachycardia. This vasodilation and tachycardia can be especially harmful as it reduces diastolic filling time on an already volume deprived LV. Dobutamine-induced hypotension should be anticipated at higher doses and may be treated with vasopressors should the need arise.

Another inotrope used in the ICU treatment of patients with PHTN is Milrinone, a PDE3 inhibitor. Milrinone directly increases cAMP which causes increased contractility and reduced afterload. Animal models of chronic PAH treated with Milrinone showed significant increases in RV function, pulmonary blood flow and LV filling.²⁶ One example of Milrinone's efficacy in human RVF can be seen in a study of patients with RVF after LVAD placement who received Milrinone and had a resulting significant reduction in PVR and an increase in LVAD flow.²⁷ As with any systemic inotrope, there is a risk of systemic hypotension with milrinone usage and vasopressors should be used as necessary to prevent hypotension.

Inhaled milrinone has been used as salvage therapy when other PAH therapies could not be increased due to hypotension.²⁸ Also, in a study of patients with PHTN undergoing mitral valve surgery inhaled milrinone decreased mean PA pressure and PVR in a similar range as IV milrinone.²⁹ As such, inhaled milrinone should be considered in the patient with hypotension and for any patient in which V/Q mismatching and shunting is a major concern.

Vasopressors

Pressure support medications should be used to maintain aortic root pressure and RCA perfusion of the RV. These medications are especially important given the loss of CO in RVF as well as the hypotensive side effects of advanced PAH therapies and inotropes. Also, by increasing the afterload, vasopressors have an additional benefit of normalizing the shape of the LV against an enlarged RV.

Norepinephrine causes vasoconstriction and improves SVR via alpha-1 receptor agonist activity as well as exerting inotropic effect by beta-1 receptor agonist activity. In a study comparing mortality and adverse event outcomes of norepinephrine versus dopamine treatment in patients with shock in the ICU, the subset of patients with cardiogenic shock treated with norepinephrine had a decreased rate of 28-days mortality and arrhythmias as compared to patients treated with dopamine.³⁰ However, in a small study of 10 patients with septic shock, PH and RVF treated with norepinephrine showed an increase in PVR and no improvement in RV EF.³¹ This increase in PVR was thought to be from a dose-dependent beta-1 effect of norepinephrine on the pulmonary vasculature.

Vasopressin acts at V1 receptors on vascular smooth muscle cells to cause vasoconstriction. Vasopressin also potentiates the vascular effects of catecholamines. Vasopressin has been shown to cause pulmonary vasodilation in animal models via endothelial NO production³² and a reduction in PVR and PVR/SVR ratio in humans,¹⁸ making it a theoretically better choice than norepinephrine for patients with PHTN. Vasopressin has been used effectively to treat sepsis induced hypotension, RVF and PHTN after cardiac surgery and chronic PHTN.¹⁸ However, vasopressin does have dose related toxicities such as coronary vasoconstriction and depressed myocardial function at higher doses and has not been studied as well as norepinephrine in the ICU setting.¹⁸ As such, for patients with pulmonary vascular dysfunction and vasodilatory shock, vasopressin can be used at low doses in those not responding to norepinephrine and other conventional treatments.

ATRIAL SEPTOSTOMY, EXTRACORPOREAL LIFE SUPPORT, AND END OF LIFE IN THE ICU

Atrial septostomy (AS) can be used to reduce RV pressures by shunting blood from the RA to LA. This shunting decompresses the dilated RV, improves LV function and RV contractility, and reduces deforming pressure on the LV from the enlarged RV. Paradoxically, this procedure does not result in decreased

oxygenation as the increased cardiac function resulting from AS outweighs the loss of hemoglobin oxygenation from the atrial shunt. However, this procedure is not appropriate for the end stages of the disease or hemodynamically unstable patients, as patients with RA pressures greater than 20 mm Hg or O_2 sat less than 80% on room air or low CI who underwent this procedure had a significantly higher risk of fatal complications.^{33,34}

For patients with end stage PAH and RVF refractory to optimized medical treatment, lung transplantation with bridging via extracorporeal life support (ECLS) should be considered. ECLS unloads the RV, increases organ perfusion and can even remove the need for catecholamine medications. As such, ECLS as a bridge to transplantation is a good choice of therapy for patients with PAH refractory to treatment exhibited by persistent hypoperfusion and continuous end organ dysfunction.

Venoarterial ECMO draws blood from the RA via a femoral venous cannula, oxygenates the blood externally to the patient, and returns the newly oxygenated blood into the lower abdominal aorta. A series of 5 patients in Germany with PH and RVF showed rapid improvement in end organ function and reversal of cardiovascular failure with V/A ECMO treatment while awake and breathing spontaneously without intubation.³⁵ Of these 5 patients, 4 survived to transplantation and 3 of these patients survived for one additional year.³⁵ A follow-up retrospective study comparing awake V/A ECMO to patients receiving traditional intubated V/A ECMO showed a significant increase in 6 months survival after lung transplantation and shortened postoperative stay in patients receiving awake V/A ECMO.³⁶ As such, awake V/A ECMO seems to be a promising bridging strategy to lung transplant for patients with PHTN. However, bleeding complications are a risk given the anticoagulation required to use V/A ECMO and 2 weeks may be the maximum time patients can remain on ECMO before other complications such as hemolysis, organ failure, sepsis, renal failure, and cerebral vascular accidents begin to occur with greater frequency.³⁷

Pumpless lung assist devices have been used in hemodynamically unstable patients with PAH and veno-occlusive disease as a bridge to lung transplantation.³⁷ Pumpless lung assist devices are

low-resistance membrane oxygenators, which are connected between the PA and the left atrium. This device effectively unloads the RV in the same way as BAS, but instead allows for oxygenation of the shunted blood over the membrane device.

If a patient does have cardiac arrest during their ICU stay, CPR has very little efficacy. One study of 132 patients with PAH who had CPR performed after circulatory arrest showed that only 8 patients survived for more than 90 days and 7 of these patients had identifiable causes of circulatory arrest.³⁸ Given the high PVR present in patients with PAH in the ICU, it is not surprising that chest compressions are unable to generate forward flow of blood from the RV through the constricted pulmonary vasculature. Timely discussions of goals of care and DNR orders are, therefore, appropriate for patients with PAH and RVF in the ICU.

Electrolyte Disorders in Critically Ill Patients

Sheron Latcha, MD, FASN

KEY POINTS

- 1 A careful assessment of the patient's osmolality and volume status are vital to appropriately evaluate the patient with either hypernatremia or hyponatremia.
- 2 The syndrome of inappropriate antidiuretic hormone is characterized by inappropriately concentrated urine in the setting of a low serum osmolality and a normal plasma volume.
- 3 Treatment strategies for syndrome of inappropriate antidiuretic hormone include fluid restriction to 1 to 1.5 L of free water per day, sodium chloride tablets, isotonic saline along with furosemide or hypertonic saline (2% or 3%) alone, and vasopressin-2 (V2) receptor antagonists (conivaptan and tolvaptan).
- 4 For patients with symptomatic and/or severe hyponatremia (mental status changes, seizures, coma, sodium < 115 mEq/L), 3% normal saline should be used to correct the sodium deficit with close monitoring of their neurologic status and serum sodium values.
- 5 The goals in treating hypernatremia include identifying correcting any reversible factors (hypercalcemia, hypokalemia, and hypertonic solutions); correcting volume depletion if present; and replacing the calculated free water deficit.
- 6 The clinical signs and symptoms of hyperkalemia are predominantly neuromuscular (weakness, and muscle paralysis) and cardiac (electrocardiographic [EKG] changes—peaked T waves, prolonged PR interval, widened QRS, arrhythmias, and asystole).
- 7 The most rapid way to lower serum potassium is with the use of inhaled beta agonists (nebulized albuterol 10-20 mg over 15 minutes) and insulin (50 s of D50W and 10U regular insulin over 15-30 minutes). Other treatments include IV sodium bicarbonate, isotonic saline infusion, loop diuretics alone or in combination with saline infusion, and sodium polystyrene given as a rectal suppository or orally in combination with sorbitol for faster delivery to its site of action at the colonic mucosa.
- 8 Clinical manifestations of hypokalemia are predominantly cardiac (arrhythmias, EKG changes [flattening of the T wave, and U wave]) and neuromuscular (muscle weakness, paralysis, ileus, and constipation).
- 9 Symptoms of severe hypocalcemia include tetany, seizures, a prolonged QT interval, and ventricular arrhythmias. For acute correction of symptomatic hypocalcemia, IV calcium gluconate, or calcium chloride

—Continued next page

Continued—

(10 mL of a 10% solution) can be administered over 10 minutes.

- 10 For patients with symptomatic hypercalcemia, aggressive volume expansion with 0.9% normal saline at rates needed to promote a urine output of 100 to 150 cc/h is recommended. Other treatments include furosemide after adequate volume resuscitation is achieved, calcitonin, bisphosphonates (pamidronate and zoledronate), and dialysis.
- 11 Hypophosphatemia may be associated with decreased myocardial contractility, respiratory failure due to diaphragmatic paralysis, dysphagia, ileus, paresthesias, seizures, rhabdomyolysis, and myopathy.
- 12 Hyperphosphatemia may result from tumor lysis syndrome, massive blood transfusions, rhabdomyolysis, acute extracellular shifts of phosphorus (lactic and diabetic ketoacidosis), ingestion of large amounts of phosphorus containing laxatives, hypoparathyroidism, and vitamin D toxicity.
- 13 Clinically important manifestations of hypomagnesemia include EKG changes (arrhythmias and torsades de pointes), neuromuscular problems (tetany and seizures), electrolyte disorders (hypokalemia and hypocalcemia) and impaired parathyroid hormone release and action.

INTRODUCTION

Fluid and electrolyte disorders are ubiquitous in the intensive care unit (ICU) setting. This text will focus on common clinical scenarios in the ICU and assumes a basic fund of knowledge about fluid and electrolyte disorders.

SODIUM DISORDERS

Sodium is the most copious extracellular (EC) cation and is the most important osmotically active constituent of the EC fluid. Changes in serum sodium represent changes in salt and water balance. Therefore, a careful assessment of the patient's osmolality and volume status are vital to appropriately evaluate the patient with either hypernatremia or hyponatremia.

Hyponatremia

Hyponatremia is one of the most common electrolyte disorders in hospitalized patients, with a reported prevalence of 30% to 40%. It has been observed in 14% of patients upon admission to the ICU and in 30% of patients in the critical care setting.^{1,2} This diagnosis is associated with statistically

significantly increased mortality, length of hospital stay, admission to the ICU, and cost for hospitalization.³ An algorithm for evaluating the patient with hyponatremia is proposed in [Figure 27-1](#).

Pseudohyponatremia and Hyperosmolar Hyponatremia

The first step in the evaluation of a hyponatremic patient is to obtain a serum osmolality in order to identify those patients with pseudohyponatremia and those who have hyperosmolar hyponatremia. As its name implies, pseudohyponatremia refers to a spuriously low-measured serum sodium value. In the presence of severe hyperlipidemia and paraproteinemia, the water phase of serum becomes displaced by these particles, and when flame photometry or indirect potentiometry is used to measure sodium, the values are reported as spuriously low. Measuring serum sodium by direct potentiometry should remove this problem. Patients with pseudohyponatremia require no further treatment.

The presence of exogenously or endogenously derived osmotically active particles in serum will cause hyperosmolar hyponatremia. In normal

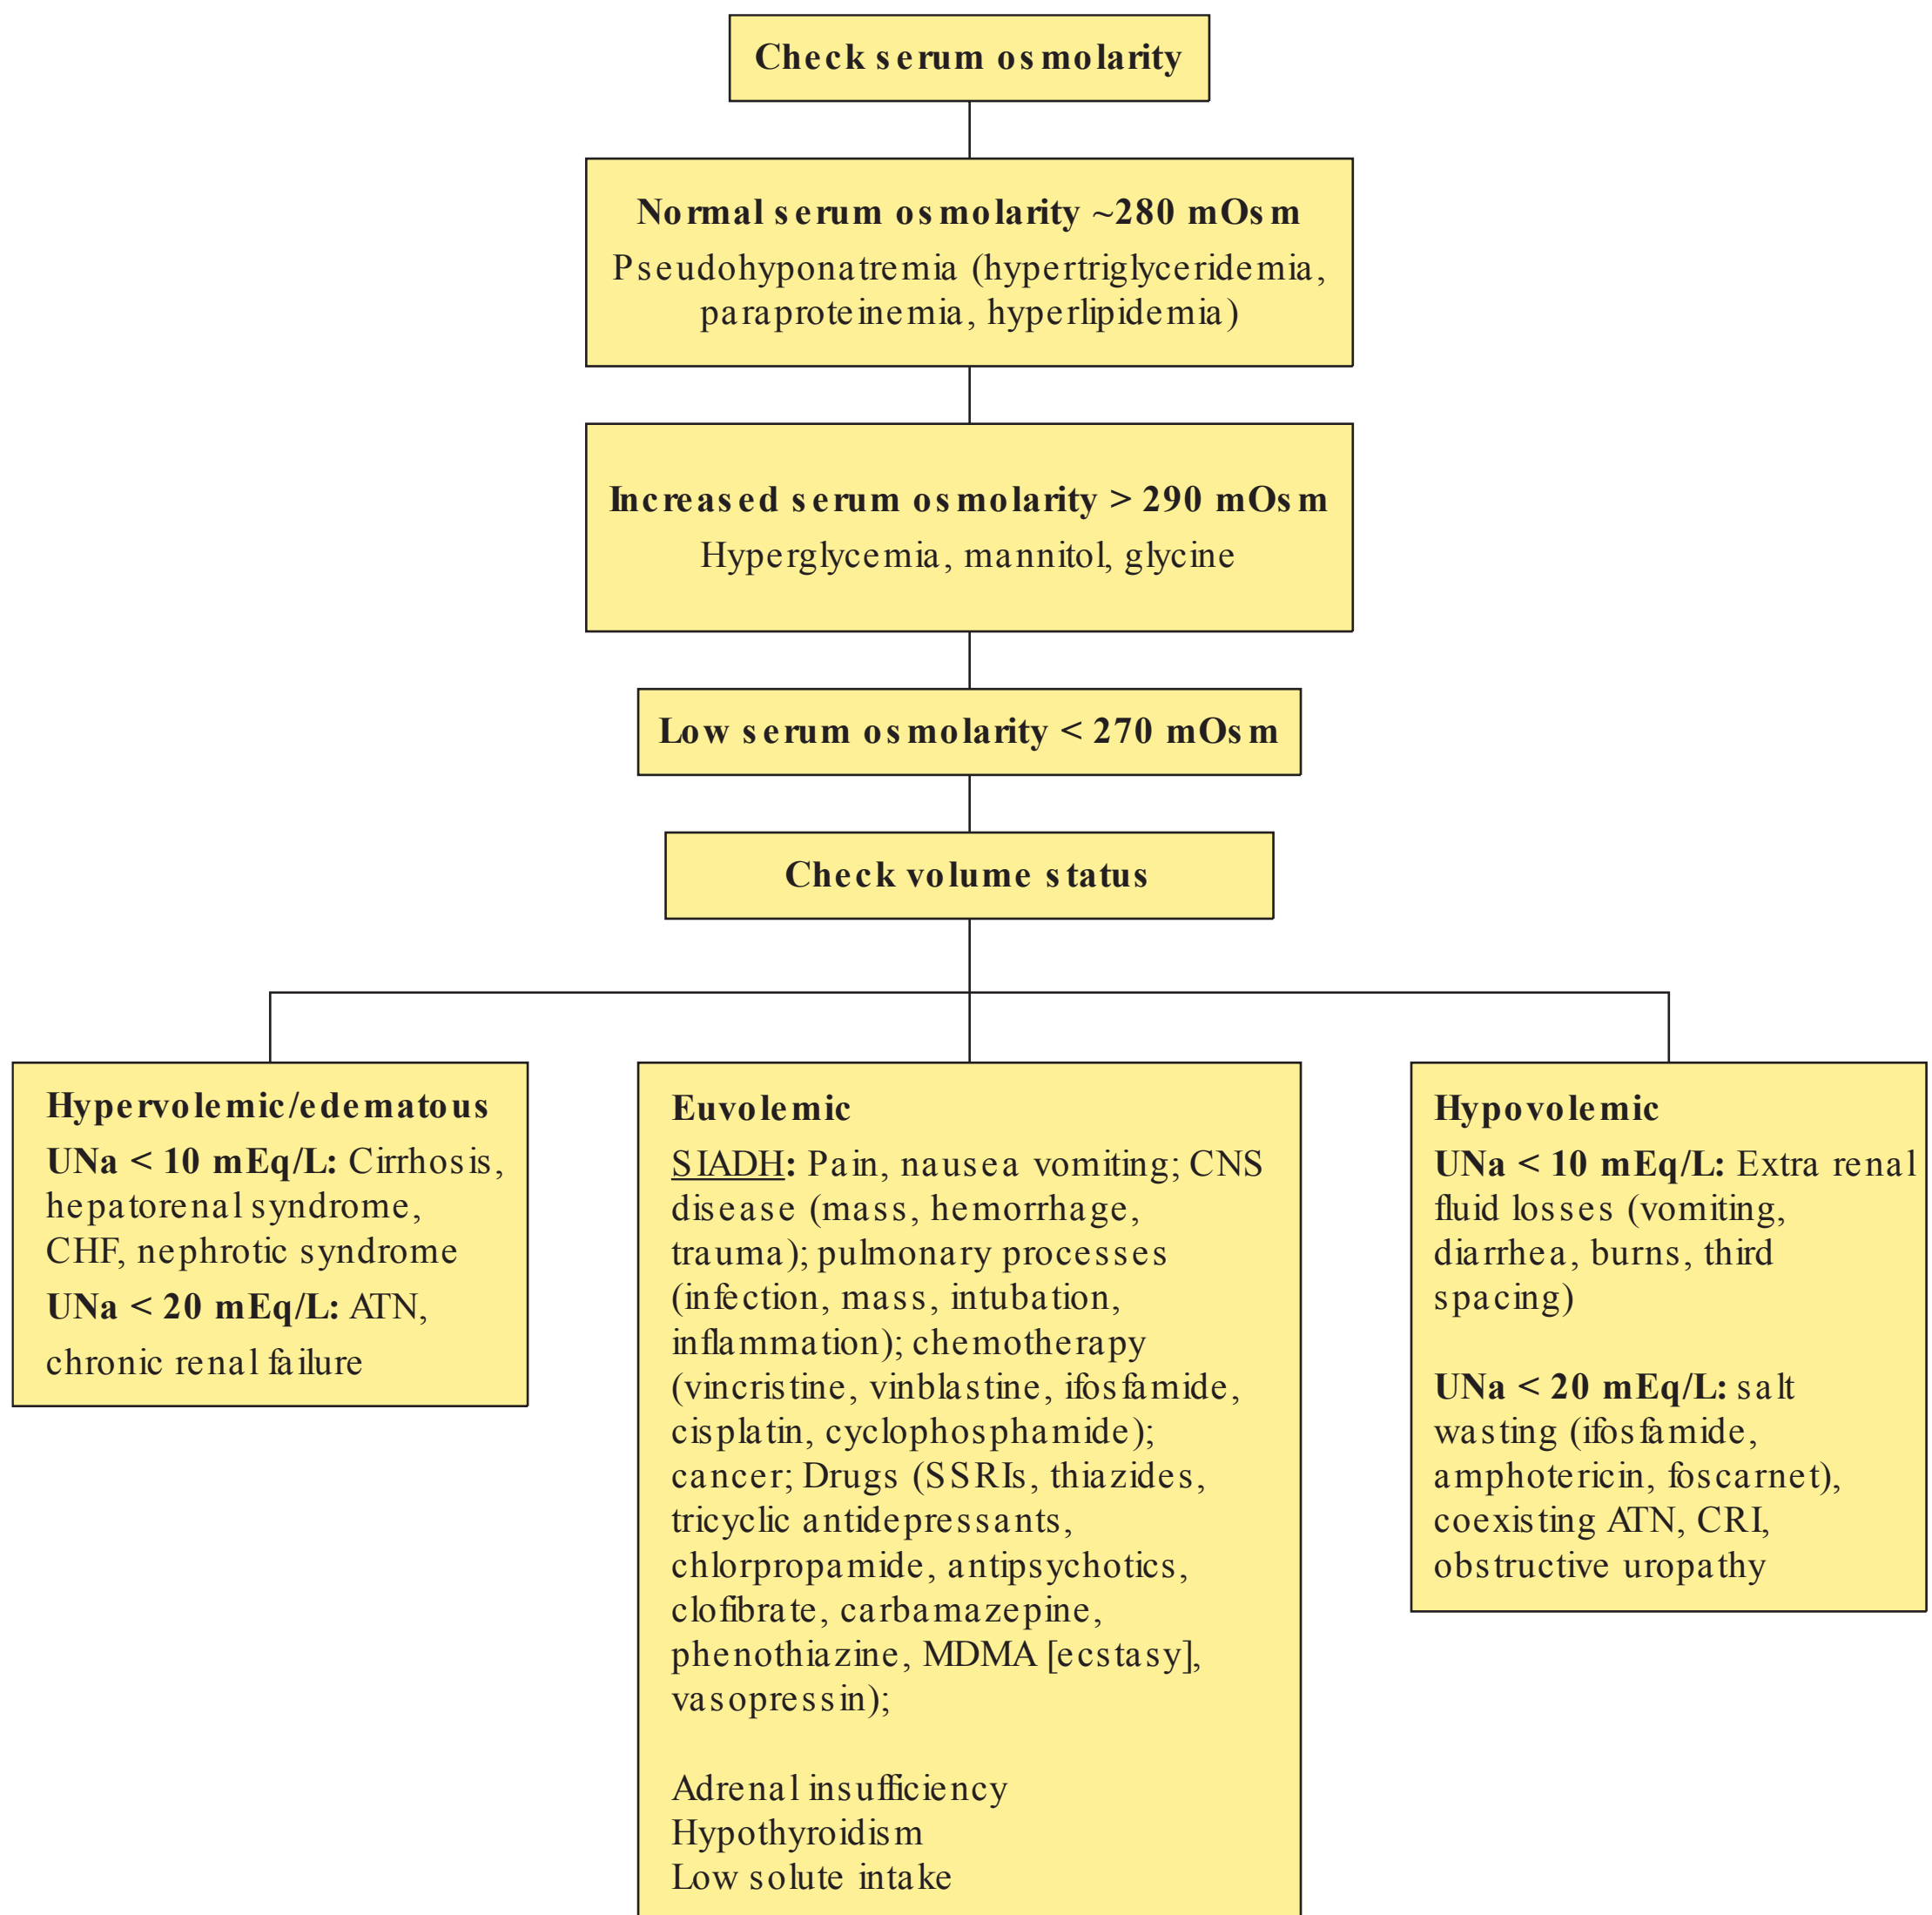

FIGURE 27–1 Clinical approach to the patient with hyponatremia.

homeostasis, water will shift across the cell membrane to equalize the osmolality between the intracellular (IC) and EC spaces. When there are osmotically active particles in the EC space, large volumes of water can transfer from the IC, causing a true dilutional hyponatremia. Patients who undergo procedures, such as hysteroscopies or transurethral resections of bladder tumor (TURBTs) are exposed to glycine containing fluids. Glycine is an osmotically active particle. Because large volumes of these

solutions are instilled into the body cavity during surgical procedures, the high intravesical pressures can cause glycine to be absorbed into the venous circulation. Subsequent translocation of free water from the IC to the EC space will cause a dilutional hyponatremia. A similar process occurs in the presence of other osmotically active particles, such as mannitol and in the setting of hyperglycemia.⁴ Importantly, the patient with hyperosmolar hyponatremia should never receive hypertonic saline

as part of the management of hyponatremia, even if they have mental status changes associated with hypernatremia, since hypertonic saline will only exacerbate the hyperosmolar state. A renal consultation should be obtained since these patients may require hemodialysis (HD).

Hypo-Osmolar Hyponatremia

Most patients will fall into the remaining category of hypo-osmolar hyponatremia. Since disorders of serum sodium are best approached as disorders of relative concentrations of salt and water, all hyponatremic patients, whether they are volume overloaded, euvolemic or hypervolemic, have an excess of total body water relative to total body sodium. Therefore, an assessment of the patient's volume status helps to define the primary disorder in this category of patients. Be mindful that the presence of edema does not accurately identify a patient as hypervolemic. Deep venous thrombosis, inferior vena cava (IVC) clots, and lymphatic or venous obstruction from pelvic masses can all produce lower extremity edema. However, these patients may have a state of diminished effective intravascular volume due to diminished venous return to the right atrium from the primary disease process. Since patients in the ICU can have nonvolume mediated causes of tachycardia and dry mucous membranes, whenever possible, it can be very helpful to check orthostatic vital signs at the bedside to assess the volume status in patients who is not frankly hypotensive. A patient is considered to be orthostatic if the heart rate increases more than 20 beats/min or the systolic blood pressure drops more than 10 mm Hg from the supine to upright position. Patients should be allowed spend 2 to 3 minutes in the sitting and standing position before the vitals are checked to allow for appropriate autoregulation.

Hypovolemic hyponatremia—This scenario can be observed in patients on diuretics, or who have diarrhea, excessive sweating (marathon runners), or insensible losses from the skin (burn victims). A similar scenario can be observed in the intubated ICU patient because the positive intrathoracic pressures generated by mechanical ventilation will impair cardiac filling. The volume deficit in these patients will cause activation of the baroreceptors, the release of antidiuretic hormone (ADH), and activation of the

renin angiotensin aldosterone system and the sympathetic nervous system. The end result of triggering these pathways is the retention of free water and salt. ADH and angiotensin are also dipsogens and will stimulate thirst. Consequently, there will be net retention of free water and salt, but a relative excess of free water retention. These patients typically have “prerenal” indices—a urine sodium less than 20 mEq/L, urine osmolality more than 500 mOsm and a fractional excretion of sodium (FENa) less than 1%. Since diuretics can affect urine sodium excretion, for patients who have received diuretics within the preceding 24 hours, the fractional excretion of urea (FEurea) can be checked instead. A FEurea of <15% suggests volume contraction.

A more complex presentation of hypovolemic hypovolemia occurs with renal salt wasting and cerebral salt wasting. Renal salt wasting has been described following exposure to chemotherapeutic agents (cisplatin and ifosfamide) and anti-infectives (amphotericin, trimethoprim-sulfamethoxazole, and amikacin).⁵ Cerebral salt wasting has been described following CNS trauma, neurosurgery, and traumatic brain injury. In contrast to the previously described group of hypovolemic patients, those individuals with salt wasting syndromes tend to have polyuria and will have inappropriately high urine sodium and osmolality values and the FENa can be more than 1%. Similar urine values can be observed in patients with the syndrome of inappropriate ADH release (SIADH) which is discussed in the section on normovolemic hyponatremia. However, the patient with SIADH, by definition, is euvolemic.

Appropriate treatment for salt wasting syndromes is isotonic normal saline (0.9% NS), which can be delivered as a bolus or infusion, depending on the severity of the volume depletion. Some patients with severe salt wasting may require hypertonic saline solutions (2% or 3% NS) to replace the amount of salt being lost in the urine.

There is a subset of critically ill patients who appear volume overloaded on exam, but have diminished effective arterial blood flow and who are hypotensive or orthostatic on exam. Patients with hepatorenal syndrome, systemic inflammatory response syndrome, and those who are “third spacing” (rhabdomyolysis and pancreatitis) will have prerenal indices. In hepatorenal syndrome,

increased nitric oxide levels results in preferential pooling of blood in the splanchnic circulation, resulting in diminished effective intraarterial blood volume (EABV) to other vital organs, including the kidneys.⁶ These patients can be frankly hypotensive in the presence of substantial edema on exam. In systemic inflammatory response syndrome, although the pathophysiology is not well delineated, several cytokines pathways, which include tumor necrosis factor, nitric oxide, and interleukins appear to be responsible for the substantial capillary leak and diminished EABV. These patients may require significant amounts of crystalloid and/or colloid fluids to expand their intravascular volume.

Hypervolemic hyponatremia—This group of visibly volume overloaded patients have excessive amounts of total body free water and sodium, with relatively more free water than sodium in the EC space. Classically, patients with congestive heart failure, cirrhosis, nephrotic syndrome (NS), and pregnancy fall into this category. In the case of a normal pregnancy, serum sodium declines up to 5 mEq/L below normal values because ADH is released at a lower set point. Hyponatremia in pregnancy is physiologic and does not require correction.⁷ On the other hand, the hyponatremia associated with congestive heart failure and cirrhosis is best treated with the use of loop diuretics. Thiazide diuretics should be avoided in the setting of hyponatremia because they can actually cause hyponatremia. This is because thiazides impeded the ability of the collecting tubules to maximally concentrate urine and will, therefore, cause overall retention of free water.

Normovolemic hyponatremia—The 2 physiologic stimuli for ADH release are an elevated serum osmolality and a diminished plasma volume. Therefore, in the setting of a low-serum osmolality and a normal plasma volume, there is no physiologic stimulus for ADH release. There are, however, numerous nonphysiologic stimuli for ADH, and these stimuli are prevalent in the ICU. Pain, nausea, drugs (catecholamines, chemotherapy, antidepressants, and diuretics), and any lung or CNS disease can cause inappropriate release of ADH. The postoperative state is also associated with inappropriate ADH release, and potentially severe hyponatremia can develop in patients receiving hypotonic intravenous (IV) solutions in the perioperative period.

Death and permanent neurologic deficits in the setting of postoperative hyponatremia is more commonly observed in menstruating women and prepubertal children.⁸ Adrenal and thyroid deficient states are also associated with SIADH. Figure 27–1 lists some causes of SIADH that can be encountered in the ICU setting.

The defining feature of the SIADH state is the presence of inappropriately concentrated urine in the setting of a low-serum osmolality and a normal plasma volume. The urine sodium is > 20 mEq/L and the FENa is more than 1%.

Importantly, administering 0.9% NS to a patient with SIADH will actually worsen the hyponatremia. Because these patients have a normal plasma volume, there is no stimulus for the kidney to retain the 9 g of sodium contained in each liter of 0.9% NS. However, the presence of ADH will cause the renal tubules to retain the IL of water. This free water retention will dilute and further lower the serum sodium. Inappropriately administering 0.9% NS to patients with SIADH who have a very low serum sodium values or abruptly lowering the sodium significant amounts can precipitate hyponatremic seizures. Therefore, 0.9% NS without furosemide or any hypotonic fluids (D5W, 1/2NS) are all contraindicated in the setting of SIADH.

Several approaches can be employed to correct the imbalance between sodium and water concentration in the setting of SIADH. Patients can be asked to restrict their fluid intake to 1 to 1.5 L of free water per day and can be given NaCl tablets. These interventions may be limited in the ICU patient since they often require IV medications and cannot tolerate oral medications. In this case, 0.9% NS given along with furosemide or hypertonic saline (2% or 3%) alone can be used to increase the serum sodium concentration. Usual doses of furosemide in patients with normal renal function are 10 to 20 mg/d and can be given IV or orally. Higher doses of furosemide may be required in patients with renal function. Vasopressin-2 (V2) receptor antagonists are the newest class of agents which can be used in the management of hypervolemic and euvolemic hyponatremia. V2 receptor antagonists will block ADH-mediated insertion of aquaporin channels at the apical membrane of the renal collecting duct cells and will ultimately result in free water losses in

the urine. Conivaptan is an IV formulation (20 mg infused over 30 minutes as a loading dose, followed by a continuous infusion of 20 mg over 24 hours) and tolvaptan can be given to patients who are able to take oral medications (initial dose is 15 mg once daily can increase to 30 mg once daily after 24 hours). Any combination of fluid restriction, NaCl tablets, furosemide, and/or a V2 receptor antagonist can be used to achieve a normal serum sodium value. Conivaptan and tolvaptan have been shown to reliably increase serum sodium by 6 to 8 mEq/L with a 48 hours period and have the advantage of not producing the hypokalemia and metabolic alkalosis that can result from treatment with diuretics.⁹

If nausea, vomiting and pain are inappropriately stimulating ADH, then appropriate use of antiemetics and pain medications can diminish these non-physiologic stimuli for ADH release. Any of the culprit medications that have been implicated as a cause of hyponatremia (see Figure 27–1) should be discontinued if it is safe to do so. For patients with adrenal or thyroid deficient states, hormone replacement therapy will be necessary to correct the hyponatremia.

Clinical Manifestations and Management of Severe Hyponatremia

The clinical signs and symptoms of hyponatremia are in large part manifestations of increased intracerebral pressure due to brain edema. When the serum sodium and serum osmolality are lower than that within the brain cells, water will shift into the brain cells. Since the skull is a fixed cavity, it cannot expand to accommodate this increase in brain volume. Some clinical signs of increased intracranial pressure include nausea, confusion vomiting, a decline in mental status, ataxia, and seizures. When hyponatremic encephalopathy develops, the associated mortality rate is as high as 20%.⁸ If the brain volume markedly exceeds the skull volume, frank herniation of the brainstem and death can occur. There are adaptive mechanisms in place to mitigate brain edema in the setting of hyponatremia. However, when the serum sodium drops too rapidly relative to the ability of the brain to adapt to the change in osmolality, clinical signs, and symptoms will develop. This explains why one patient can present

with seizures and another can appear asymptomatic at equivalent serum sodium values.

The brain's adaptive mechanisms are essentially aimed at decreasing its water content back to normal by extruding solute. In rat models, Na^{2+} and Cl^{-} are extruded via the Na^{2+} and Cl^{-} channels present in the cell membrane within 30 minutes of induction of hyponatremia. These electrolyte losses are maximal at around 3 hours. After longer periods of persistent hyponatremia, organic osmolytes such as glutamate, creatine, and taurine exit the brain cell.¹⁰ These compensatory adaptations explain why rapid correction of chronic hyponatremia leads to rapid egress of water from the brain cell. In mild cases, dehydration of the brain tissue occurs, and in severe cases, osmotic demyelination can occur. The current recommendation for correcting chronic hyponatremia or hyponatremia of unknown duration is to correct the serum sodium no more than 10–12 mEq/L within the first 24 hours, and at a rate of no more than 10 to 12 mEq/L within the first 24 hours, and generally, at a rate of no more than 0.5 mEq/L/h.¹¹

Treatment for mild hyponatremia is discussed in the aforementioned sections. When symptomatic hyponatremic develops (mental status changes, seizures, and coma), and when serum sodium levels are very low (less than 115 mEq/L), patients need to be closely monitored with repeated neurologic evaluations and frequent monitoring of their serum sodium values while they receive 3% NS to correct the sodium deficit. One of the numerous online resources available to calculate the sodium deficit is <http://www.mdcalc.com/sodium-deficit-in-hyponatremia/>, or the sodium deficit can be calculated using the equation: Sodium deficit = total body water \times (desired serum Na – actual serum Na), where total body water is total body weight (kg) \times 0.5. Each IL of 3% NS contains 512 mEq of sodium. Importantly, the severely symptomatic patient with hyperosmolar hyponatremia should not receive 3% NS. Administration of a hypertonic solution in this setting is contraindicated as it will worsen the hyperosmolar state. This category of patients may require urgent dialysis. Patients with significant hypovolemia should be treated with boluses of NS until a euvolemic state is achieved. Thereafter, the rate of correction of the serum sodium should not exceed 10 to 12 mEq/L in a 24 hours period.

Hypernatremia

The incidence of hypernatremia in the general hospital population is only 1%. The reported incidence in the ICU population ranges from 10% to 26%, and it is most commonly hospital acquired.¹² When hypernatremia is acquired in the ICU, the adjusted hazard ratio for ICU mortality increased twofold in patients with mild hypernatremia (> 145 mEq/L) and 2.67-fold in patients with moderate to severe hypernatremia (> 150 mEq/L).¹³

Hypernatremia arises when there is a relative or absolute free water deficit so patients are either hypervolemic or hypovolemic, respectively. Normally, a rise in serum sodium, and consequent rise in serum osmolality causes ADH release, which is a potent stimulus for thirst. Patients with an intact thirst mechanism and access to free water are able to maintain normal serum sodium levels notwithstanding considerable urine outputs in hyperosmolar states from hyperglycemia or diabetes insipidus. By contrast, ICU patients oftentimes have an impaired thirst response, impaired access to free water or restricted fluid intake.

Hypervolemia Hypernatremia

Administration of sodium bicarbonate, trisodium citrate, hypertonic saline, or other fluids containing an excess of solute relative to free water results in hypervolemic hypernatremia.

Hypovolemic Hypernatremia

Conditions that cause excessive amounts of free water losses via the kidneys include central and nephrogenic diabetes insipidus (CDI and NDI, respectively). Acquired causes of NDI include amphotericin, foscarnet, lithium, hypokalemia, and hypercalcemia. Hyperglycemia and mannitol cause an osmotic diuresis and hyperalimentation solutions can also produce diuresis due to urea generation. Nonrenal free water losses can occur via the gastrointestinal (GI) tract (nasogastric suction, diarrhea, and vomiting), skin (burns, hyperthermia, open wounds, and drains), and from the respiratory tract in intubated patients.

Clinical Manifestations and Management

The clinical signs of hypernatremia are the result of shrinkage of the brain away from the skull and the mechanical stress that this causes on blood vessels,

which can lead to ischemia and hemorrhage. Symptoms include agitation, lethargy, seizures, and coma. When hypernatremia develops rapidly, osmotic demyelination can occur.

The goals in treating hypernatremia include (1) identifying correcting any reversible factors (hypercalcemia, hypokalemia hypertonic solutions); (2) correcting volume depletion if present; and (3) replacing the calculated free water deficit. Additionally, if compatible, all IV medications should be administered in hypotonic solutions (1/2 NS or D5W). In hypervolemic patients, thiazides can be used to decrease edema as well as the serum sodium. In patients with polyuria due to partial NDI or CDI, arginine vasopressin administration will permit free water retention in the kidneys and correction of the sodium to a normal value permitting free water retention in the kidneys. In the hypovolemic patient with hemodynamic compromise, isotonic NS can be given to first correct the volume deficit and to ward off hemodynamic collapse. Thereafter, hypotonic solutions (1/2 NS or D5W) can be used with the goal of correcting 1/2 the free water deficit in the initial 24 hours period, and the remaining deficit over the ensuing 48 to 72 hours. The free water deficit can be calculated using the formula: Water deficit = $0.5 \text{ Wt (kg) [Serum Na/140-1]}$. Ongoing losses should be considered when replacing the water deficit. The serum sodium should not decrease by more than 0.5 mEq/L/h. Overly rapid correction of hypernatremia can cause increased intracranial pressure and the signs associated with hyponatremia (see section on hyponatremia).

POTASSIUM

Approximately 98% of the body's potassium is found in the IC space. Normally, when potassium enters the circulation acutely, it is rapidly shifted to the IC space by the action of insulin and catecholamines. The kidneys are the major site for excretion of potassium and chronic potassium homeostasis. Eighty percent of potassium is excreted from the kidneys, and 90% is reabsorbed via the renal tubules. Aldosterone is the major hormone governing renal potassium excretion.¹⁴ About 15% of potassium is eliminated from the GI tract and 5% is lost in sweat.¹⁵ The major clinical manifestations

potassium disorders are cardiac and neuromuscular abnormalities.

Hyperkalemia

Keeping in mind the key regulators of potassium homeostasis mentioned in the previous paragraph, a simple and effective approach to evaluating hyperkalemia is to make the following inquiries: (1) Is there is too much exogenous potassium being delivered to the patient? (2) Is there is a problem with the usual mechanism for shifting potassium into the IC space? (3) Is there is a problem with eliminating potassium via the kidneys or GI tract? A number of conditions can predispose ICU patient to developing hyperkalemia, including insulin deficiency or resistance, renal dysfunction, adrenal insufficiency, and exposures to medications that are known to derange normal potassium homeostasis.

Acute potassium loads from cell destruction in the setting tumor lysis syndrome, massive blood transfusions and rhabdomyolysis can overwhelm the normal mechanisms available to acutely shift potassium into the IC space. In patients with hyperglycemia, insulin deficiency will cause diminished influx of potassium to the IC space. Moreover, when hyperglycemia is present, in response to the osmotic gradient generated across the cell membrane by the hyperglycemia, water will shift from teh IC to the EC space to equalize the gradient across the cell membrane. By the process of solvent drag, potassium will move with the water to the EC space, further increasing serum potassium levels.

A host of medications commonly used in the ICU can (1) impair the kidney's ability to appropriately excrete potassium (triamterene, trimethoprim, pentamidine, and spironolactone); (2) inhibit the ATPase driven movement of potassium into cells (beta-blockers and digoxin); (3) inhibit aldosterone synthesis (angiotensin converting enzyme inhibitors, angiotensin 2 receptor blockers, heparin, and azole antifungals); (4) inhibit prostaglandin (non-steroidal anti-inflammatory medications); and (5) suppress the release of low renin and consequently low aldosterone levels (cyclosporine and tacrolimus).¹⁶

Patients who are volume-depleted patient are unable to properly excrete potassium, since the delivery of sodium to the distal renal tubule is

necessary for urinary potassium secretion. Patients with obstructive uropathy also have an impaired ability to excrete potassium properly. Potential sources of exogenous potassium that can go unnoticed in the ICU patient include the administration of inappropriate enteral or parenteral nutrition, and chronic absorption of potassium from degenerated RBCs from a retroperitoneal hematoma or GI bleed.

Clinical Manifestations and Management

The clinical signs and symptoms of hyperkalemia are predominantly neuromuscular (muscle weakness, paralysis) and cardiac (electrocardiographic [EKG] changes—peaked T waves, prolonged PR interval, widened QRS, arrhythmias, and asystole).

The patient with hyperkalemia is best approached with following principles in mind: (1) identify and discontinue all medications that may be deranging normal potassium homeostasis; (2) discontinue all potassium containing IV fluids; (3) shift potassium into the IC space; and (4) increase potassium elimination through the kidneys and the GI tract.

For patients who have EKG changes associated with hyperkalemia, IV calcium (10% calcium chloride or calcium gluconate 500-1000 mg over 2-5 minutes) is needed to stabilize the cardiac cells and lower the risk of fatal arrhythmias. Patients with muscle weakness or paralysis and those who have acute renal failure may require urgent dialysis. An early renal consultation is recommended for these patients.

The most rapid way to lower serum potassium is with the use of inhaled beta agonists (nebulized albuterol 10-20 mg over 15 minutes) and insulin (50 mL of D50W + 10U regular insulin over 15-30 minutes). These agents will acutely shift potassium into the IC space. In the hyperglycemic patient, insulin therapy will dissipate the gradient for solvent drag across the cell membrane in addition to pushing potassium back into the IC space. If a patient is acidemic, neutralizing the serum pH with IV sodium bicarbonate (50 mEq intravenous push (IVP)) will facilitate potassium entry back into cells. While beta agonists and insulin acutely shift potassium into cells, these measures are short lived and rebound hyperkalemia can occur if additional steps are not taken at the same time to permanently remove potassium from

the body. Infusion with 0.9% NS will promote a kaliuresis by increasing delivery of sodium to the distal tubule. If clinically appropriate, a loop diuretic can be used alone or in combination with IV 0.9% NS to promote renal potassium elimination. Potassium losses can also be affected via the GI tract. Sodium polystyrene (15-30 g) will exchange potassium for sodium across the colonic mucosa. However, it may take several days to appreciably lower the serum potassium since delivery to the colon is dependent on GI transit time. Sodium polystyrene can be given as a rectal suppository or orally in combination with sorbitol for faster delivery to its site of action at the colonic mucosa. Care should be taken when prescribing this medication to patients in the post-operative period following abdominal surgery and in patients who are hypotensive or have decreased GI motility. These patients may be at increased risk of bowel necrosis with this therapy.¹⁷ Sodium polystyrene and sodium bicarbonate can both worsen fluid retention in patients with volume overload and should be used with caution in this setting.

Hypokalemia

The frequency of hypokalemia in the adult ICU population has not been well documented, but it is encountered fairly commonly. In the pediatric ICU population, the reported frequency is 40%.¹⁸ The same principles apply when approaching hypokalemia as is the case with hyperkalemia. That is to say, it is necessary to systematically identify factors that will (1) shift potassium into the IC space (beta agonists, epinephrine, insulin, dobutamine, respiratory alkalosis, and refeeding); (2) increase GI losses of potassium (nasogastric tube (NGT) suction; vomiting, diarrhea, and sodium polystyrene sulfonate); (3) increase renal potassium losses (diuretics, hypomagnesemia, aminoglycosides, amphotericin, cisplatin, ifosfamide, fludrocortisone, postobstructive diuresis, and post-acute tubular necrosis (ATN) diuresis); and (4) diminish oral potassium intake. In the setting of a post-ATN and a postobstructive diuresis, renal tubular resorptive function is impaired so patients can excrete large amounts of isosthenuric urine containing significant amounts of electrolytes. In the refeeding syndrome, the introduction of carbohydrates and subsequent increase in insulin release will shift potassium to the IC compartment.

Clinical Manifestations and Treatment

The clinical manifestations of hypokalemia are predominantly cardiac (arrhythmias, EKG changes [flattening of the T wave, U wave]) and neuromuscular (muscle weakness, cramping and ileus, and constipation). Fairly small decrements in serum potassium values can actually represent significant potassium deficits since most of the potassium stores are in the IC space. For example, mild hypokalemia with a serum K of 3.0 mEq/L can actually reflect up to a 300 mEq total body deficit.¹⁹ There is no reliable way to measure the total body potassium deficit.

In general, ICU patients receive potassium replacement intravenously, but oral administration of potassium is preferable if possible. Potassium infusions can be caustic to peripheral veins, so for doses exceeding 10 mEq/h, a central line should be used. Continuous EKG monitoring is appropriate in those patients with an abnormal EKG for whom it may be necessary to infuse potassium at rates exceeding 20 mEq/h. In all patients, especially those with renal impairment, serum potassium levels should be repeated after electrolyte replacement to ensure adequate correction and to avoid over correction. In patients with concomitant hypomagnesemia, the hypomagnesemia needs to be corrected first because hypomagnesemia will cause efflux of potassium from the renal tubules and can result in resistance to potassium supplementation. For ICU patients with diuretic-induced hypokalemia who require further diuretic therapy, in addition to correcting the hypokalemia, consideration should be given to adding to or replacing the loop diuretic with a potassium sparing diuretic such as spironolactone, triamterene, or amiloride.

CALCIUM

Serum calcium reflects less than 1% of total body calcium, as 99% of total body calcium resides in the bones. Of the remaining 1% of serum calcium, 50% is bound to albumin and 50% is unbound or biologically active calcium. Common conditions in ICU patients can affect the amount of unbound (free) calcium. For example, in the setting of metabolic alkalosis, there is increased calcium binding to albumin and in the setting of metabolic acidosis, decreased calcium binding to albumin. Because ICU patients

are often hypoalbuminemic and have derangements in their acid base status, measuring ionized serum calcium levels is the best method for determining an individual's true serum calcium status.²⁰

The chief regulators of serum calcium levels are parathyroid hormone (PTH), vitamin D levels, and calcitonin. Calcium acts as a key IC regulator and messenger. As a result, some clinically important manifestations of disordered calcium homeostasis in the ICU patient include neuromuscular and cardiac dysfunction. Symptoms of severe hypocalcemia include tetany, seizures, a prolonged QT interval, and ventricular arrhythmias.

Hypocalcemia

Hypocalcemia is ubiquitous in the ICU, affecting 80% to 90% of all patients,¹⁶ and when present, is associated with longer ICU stays, increased mortality and higher rates of bacteremia.²¹ It can be the result of low vitamin D levels and abnormalities in the release or effect of PTH. Hypoparathyroidism and hypomagnesemia can both decrease PTH secretion and hypomagnesemia additionally diminishes the effect of PTH on skeletal tissue and so will decrease calcium release from bone.

The patients who come to the ICU following a parathyroidectomy can have severe and abrupt hypocalcemia. Following resection of the parathyroid gland for secondary or tertiary hypoparathyroidism, the tonic release of high levels of PTH suddenly dramatically decreases. Serum calcium rushes into the skeletal compartment and can result in severe symptomatic hypocalcemia. This is referred to as the “hungry bone syndrome.”

In cancer patients, tumor lysis syndrome can occur spontaneously or following chemotherapy. As the tumor cells release their IC contents, the resultant acute hyperphosphatemia becomes the source for calcium phosphate precipitates and this will abruptly lower the serum calcium. A similar scenario of acute calcium phosphorus precipitate formation occurs in the setting of rhabdomyolysis and following exposure to phosphorus containing laxatives and enemas which are commonly used prior to colonoscopies. Hyperphosphatemia will further lower serum calcium levels by causing decreased levels of 1,25(OH)₂ vitamin D.

In patients who transfused with large amounts of blood products, and in those patients receiving citrate anticoagulation during plasmapheresis or continuous renal replacement therapy (CRRT), hypocalcemia can result from citrate acting as a chelator of ionized calcium. Gadolinium contrast interferes with calcium assays and can cause spurious hypocalcemia. However, the ionized serum calcium measurements are not affected.²²

Clinical Manifestations and Treatment

For acute correction of symptomatic hypocalcemia, IV calcium gluconate or calcium chloride (10 mL of a 10% solution) can be administered over 10 minutes. For patients with hungry bone syndrome, in addition to IV pushes of calcium chloride or calcium gluconate, a continuous IV calcium infusion, with frequent monitoring of serum calcium, may be necessary to maintain normal serum calcium levels. When hypocalcemia is accompanied by hypomagnesemia, the hypomagnesemia will need to be corrected first or the hypocalcemia can become resistant to calcium supplementation due to the effect of hypomagnesemia on PTH release and action on its end organs. When hypocalcemia is accompanied by metabolic acidosis, the hypocalcemia should be corrected before the acidosis because correcting the acidosis first will further lower the serum calcium and possibly precipitate symptomatic hypocalcemia. In patients with hypocalcemia due to formation of calcium phosphorus complexes (pancreatitis, tumor lysis syndrome), hypocalcemia should only be corrected if patients become symptomatic. If the calcium phosphorus product exceeds 60, then dialysis should be considered to lower the calcium phosphorus product prior to calcium repletion.

Hypercalcemia

Hypercalcemia occurs less often than hypocalcemia in the ICU. When present, the level of hypercalcemia can be an important clue to its pathogenesis. Serum calcium values above 13 mg/dL should raise suspicion for hypercalcemia of malignancy in the appropriate clinical setting. Hypercalcemia of malignancy is most often attributable to PTH related protein and, less frequently, to osteolytic cytokines and exogenous calcitriol production. Less severe levels

of hypercalcemia can be seen in association diseases that increase bone resorption (immobility, thyrotoxicosis, and Paget's and hypervitaminosis A); diseases that increase intestinal absorption of calcium (milk alkali syndrome and hypervitaminosis D); any cause of increased PTH levels (primary, secondary, or tertiary hyperparathyroidism); elevated Vitamin D levels (from oral supplements, or granulomatous diseases, such as tuberculosis or sarcoidosis); and medications (thiazide diuretics, lithium, theophylline, and teriparatide). Adrenal insufficiency causes hypercalcemia via several mechanisms (volume contraction, increased bone resorption, and increased tubular absorption of calcium).

Clinical Manifestations and Treatment

Some neurologic manifestations of hypercalcemia include anorexia, confusion, and obtundation. Cardiac manifestations include arrhythmias and EKG changes (shortened QT). Importantly, hypercalcemia can cause a NDI. Free water losses in the urine from the NDI, in addition to diminished oral intake due to decrease mental acuity and anorexia in these patients, results in significant volume depletion in hypercalcemic patients. Therefore, aggressive volume resuscitation is a cornerstones of therapy for hypercalcemia.

The primary goals in the management of hypercalcemia are to (1) increase urinary excretion of calcium and (2) inhibit bone resorption. To this end, in the absence of edema, aggressive volume expansion with 0.9% NS at rates needed to promote a urine output of 100 to 150 cc/h is recommended. These patients often may require a 1 to 2 L bolus of 0.9% NS to replace the fluid deficit and then require an infusion rate of 150 to 200 mL/h. Once the patient is adequately volume replete, furosemide can be used to promote a calciuresis. It is recommended that furosemide not be given prior to adequate volume resuscitation since the diuretic can further compromise the hemodynamic status of these dehydrated patients. Calcitonin (4 units/kg every SQ every 12 hours for 4-6 doses) will begin to lower serum calcium within 4 to 6 hours of administration, with a maximum effect of 1 to 2 mg/dL (0.3-0.5 mmol/L). It does so by inhibiting bone resorption and by increasing urinary calcium excretion. Unfortunately, tachyphylaxis due to downregulation of its receptors occurs after repeated

dosing so the medication loses efficacy after 48 hours. In patients who are volume overloaded or anuric, dialysis with a low calcium dialysate (2.5 mEq/L) may be necessary to treat hypercalcemia.

Bisphosphonates (BPs) have become another cornerstone for management of hypercalcemia. Pamidronate and zoledronate currently have Food and Drug Administration (FDA) approval for the management of hypercalcemia, but pamidronate should be preferentially used in patients with renal insufficiency and a creatine clearance less than 30 mL/min. Please consult dosing guidelines for zoledronic acid for patients with mildly impaired renal function. Since the onset of action of BPs is 2 to 4 days, it is recommended that they be administered at the time that hypercalcemia is first diagnosed.

PHOSPHORUS

Phosphorus is another anion which is primarily contained in the bones and soft tissue, with only 1% circulating in the EC space. Phosphorus is the building block for adenosine triphosphate, which is required for all energy requiring physiologic and metabolic functions. Therefore, IC phosphate depletion can produce multiorgan dysfunction due to decrease oxygen release to the cardiac (decreased myocardial contractility), pulmonary (respiratory failure due to diaphragmatic paralysis), GI (dysphagia and ileus), neurologic (parasthesias and seizures) and skeletal systems (rhabdomyolysis and myopathy).

Hypophosphatemia

In the general hospital wards, about 5% of patients have serum phosphorus levels less than 2.5 mg/dL, while the prevalence of hypophosphatemia in patients with severe sepsis and trauma is reported to be 30% to 50%.²³ Patients in the ICU have conditions which predispose them to developing hypophosphatemia via the three major mechanisms: (1) redistribution of phosphorus to the IC space (due to respiratory alkalosis, glucose, and insulin release during carbohydrate refeeding in malnourished patients); (2) redistribution of phosphorus into the bone (hungry bone syndrome [see section on hypocalcemia] and bisphosphonate therapy); (3) decreased intestinal absorption of phosphorus (steatorrhea, chronic diarrhea, or prolonged starvation, phosphate binding in the gut by

aluminum or magnesium containing antacids); and (4) increased phosphaturia (any cause of increased PTH, vitamin D deficiency, acetazolamide, thiazide diuretics, or Fanconi syndrome [multiple myeloma and ifosfamide]). Patients on continuous CRRT will also lose phosphorus to the dialysate.

Treatment

Phosphorus replacement is available as potassium phosphate and sodium phosphate. Keep in mind that each mmol of potassium phosphate contains 1.47 mEq of potassium. Therefore, 15 mmol of potassium phosphate will deliver 22.5 mEq of potassium to the patient. For patients with symptomatic hypophosphatemia, phosphorus can be given at a rate of up to 7 mmol/h.²⁴ Serum phosphorus levels should be checked 2 to 4 hours after IV repletion since phosphorus can quickly shift into the IC space. Whenever possible, oral phosphorus is preferred for the correction of asymptomatic hypophosphatemia and when the serum phosphorus level is more than 2 mg/dL.

Hyperphosphatemia

Since the kidneys are very efficient at maintaining normal phosphorus balance, there has to be some element of renal dysfunction present for hyperphosphatemia to develop. Most of the total body phosphorus is contained within cells and the skeletal tissue. Therefore, release massive amounts of IC phosphorus from cell lysis (tumor lysis syndrome and massive blood transfusions), muscle injury (rhabdomyolysis), and acute EC shifts of phosphorus (lactic and diabetic ketoacidosis) will acutely increase serum phosphorus. Acute elevations in the levels of serum phosphorus have been also been reported following ingestion of large amounts of phosphorus containing laxatives used for colonoscopy bowel preparation. Hypoparathyroidism and vitamin D toxicity are also causes of hyperphosphatemia.

When there is an acute increase in serum phosphorus levels, phosphorus will complex with calcium to form calcium phosphate crystals, which in turn can cause obstructive uropathy and acute kidney injury. The acute kidney injury will in turn further compromise renal clearance of phosphorus.

Treatment

In addition to identifying and correcting underlying causes of hyperphosphatemia and infusion of NS to promote phosphaturia is central in the management of this disorder. In those patients with oral intake, oral phosphate binders can be used to bind phosphorus in the gut. However, oral phosphate binders have no benefit to those patients who are not being fed orally. HD may be required to lower the serum phosphorus in patients who are anuric or oliguria AND for those with a calcium phosphorus product more than 55-60; and in the patient with symptomatic hypocalcemia. Continuous dialysis (CRRT) will lower the phosphorus more continuously than intermittent HD and there may be rebound hyperphosphatemia in between treatments when intermittent HD is used.

MAGNESIUM

Magnesium is principally an IC cation, with only 1% of the total body content contained in the EC space. Magnesium homeostasis is predominantly handled by the kidneys with important contributions from the GI tract and parathyroid hormone. Importantly, the cation serves as a cofactor for reactions involving adenosine triphosphate. Hypomagnesemia can result from renal losses (aminoglycosides, thiazide and loop diuretics, amphotericin, cisplatin, epithelial growth factor inhibitors [cetuximab] alcoholism, and cyclosporine), GI losses (proton pump inhibitors, short bowel syndrome, malabsorption, and steatorrhea), and diminished intake (malnutrition). Magnesium can also be chelated in circulation by citrate (massive blood transfusions) and foscarnet. Hypokalemia and hypocalcemia frequently coexist with hypomagnesemia. The hypokalemia may be due to impaired function of the sodium potassium pump and the hypocalcemia is due to impaired PTH secretion and activity. Hypermagnesemia is often the result of iatrogenesis and oftentimes occurs in the setting of impaired renal function.

Hypomagnesemia

Hypomagnesemia is frequently found in critically ill patients, with a reported prevalence of 60% to 65%.²⁵ When it is present, it is associated with greater morbidity and mortality.²⁶ Clinically important

manifestations of hypomagnesemia include EKG changes (arrhythmias and torsades de pointes), neuromuscular problems (tetany and seizures), electrolyte disorders (hypokalemia and hypocalcemia), and impaired PTH release and action.

Treatment

In patients with cardiac and neuromuscular manifestations of hypomagnesemia, 1 to 2 g of magnesium sulfate can be given as a IV bolus or over 60 minutes, followed by an IV infusion to keep the serum magnesium more than 1.5 mEq/L.²⁷ When repleting magnesium, it is important to keep in mind that magnesium distributes into the tissue space very slowly, and that acute increases in serum magnesium inhibits magnesium reabsorption in the renal tubules. Therefore, when magnesium is given rapidly, up to 50% of the IV dose is lost in the urine. Therefore, the best way to supplement magnesium intravenously is to do so very slowly, at a rate not exceeding 1 g/h. It is best to allow several hours to elapse before checking the postrepletion serum magnesium levels since levels drawn immediately after supplementation may be spuriously elevated. In ICU patients with asymptomatic hypomagnesemia who are able to tolerate oral magnesium, the oral route for magnesium repletion is preferable. Unfortunately, oral magnesium supplements can cause diarrhea.

Hypermagnesemia

Since the kidneys are rapidly able to excrete magnesium when serum magnesium increases acutely, hypermagnesemia most frequently occurs when patients with underlying renal insufficiency are given a large dose of magnesium. For example, when ICU patients are given magnesium containing laxatives or antacids.

Clinical manifestations of hyperkalemia include neurologic (loss of deep tendon reflexes), cardiac (bradycardia, hypotension, heart block, and cardiac arrest), neuromuscular disturbances (respiratory paralysis), and death.

Treatment

In all cases of hypermagnesemia, the exogenous magnesium needs to be discontinued. In patients with asymptomatic hypomagnesemia, loop diuretics can be used in nonoliguric patients and dialysis

may be required in oliguric and anuric patients. When the patient is symptomatic, IV calcium chloride 500 to 1000 mg (via a central line), or IV calcium gluconate 1 to 3 g (if a central line is not available) can be rapidly infused until the neuromuscular and cardiac disturbances are reversed. HD may be required as well.

Acid-Base Disorders

James A. Kruse, MD

KEY POINTS

- 1 Recognition of acid-base disturbances through interpretation of arterial blood gases is of fundamental importance to the daily clinical practice of critical care.
- 2 The carbonic acid-bicarbonate buffer is the most important buffer system. The relation of pH to this buffering system is defined by the Henderson–Hasselbalch equation.
- 3 There are four cardinal acid-base disorders: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis.
- 4 The etiologies of metabolic acidosis can be classified by the typical serum anion gap association (elevated or normal anion gap acidosis).
- 5 The serum osmole gap is often used as a screening test when methanol or ethylene glycol intoxication is suspected.
- 6 Gastric fluid loss, diuretic use, and extracellular volume contraction are among the most common causes of metabolic alkalosis.
- 7 The etiologies of metabolic alkalosis can be classified by the expected urine chloride concentration or excretion (normal, high, or low urine chloride).
- 8 Common causes of respiratory acidosis are pulmonary disorders (eg, chronic obstructive lung disease, severe pneumonia, aspiration pneumonitis, and smoke inhalation), neurologic injury, neuromuscular and metabolic disorders, and narcotic and sedative agents.
- 9 Respiratory alkalosis is common with severe sepsis, hepatic failure, mechanical ventilation, and with drugs such as salicylates and illicit stimulants (eg, cocaine and amphetamine).
- 10 Mixed acid-base disorders are not uncommon in critically ill patients and frequently complicate interpretation of arterial blood gases in the intensive care unit setting.

INTRODUCTION

Recognition of acid-base disturbances through interpretation of arterial blood gases is of fundamental importance to the day-to-day clinical practice of critical care. Knowledge of the underlying basic chemical relationships and established nomenclature

is prerequisite to this understanding. Several different paradigms of acid-base relationships have been proposed and are in current clinical use for framing the results of blood gas and related laboratory measurements. These paradigms include the base excess method, the Stewart or physicochemical

method, and the bicarbonate-pH- P_{CO_2} method, and they all basically arrive at common endpoints of interpretation.^{1,2} The bicarbonate-pH- P_{CO_2} method, also known as the physiological method, will be described herein. It is based on the carbonic acid-bicarbonate buffer system, is well established, has an empiric basis, and is in wide clinical use. Starting with a review of acid-base terminology and basic chemical relationships, this chapter will describe the basis of the physiological method for arriving at a diagnosis of simple and mixed acid-base disorders, and show how readily available laboratory testing, in conjunction with clinical information from the history and physical examination, can narrow the differential diagnosis with the goal of pin-pointing the underlying causative process or disease.

CHEMICAL RELATIONSHIPS

One definition for an acid is a chemical compound capable of donating a hydrogen ion (ie, a proton). The degree of acidity of a solution can thus be quantified as the hydrogen ion activity, which is closely related to the molar concentration of hydrogen ions. Normal hydrogen ion concentration of plasma averages about 40 nmol/L, which is considerably less than other plasma cations commonly assayed in the clinical setting. For example, plasma sodium concentration normally averages about 140 mmol/L, which is 3.5 million-fold higher than normal H^+ concentration. To avoid using small numbers and to allow simple expression of H^+ activity or concentration over a wide range of values, the pH scale was developed. The relationship between pH and hydrogen ion concentration is defined by

$$\text{pH} = -\log_{10}[\text{H}^+] \quad (28-1)$$

where the square brackets here signify molar concentration units.

A buffer is a solution containing a weak acid (HA) and its conjugate base (A^-), which can coexist in an equilibrated reversible chemical reaction represented generically as

The molar proportions of the substances represented in this chemical equation assume definite proportional relationships to one another at

equilibrium, dependent on the chemical nature of the specific acid, temperature, and certain other variables. These proportions are expressible numerically by the modified equilibrium constant (K') as

$$K' = \frac{[\text{H}^+] \times [\text{A}^-]}{[\text{HA}]} \quad (28-3)$$

The prime symbol is added to signify that molar concentrations are employed rather than thermodynamic activities.³ Buffers resist changes in pH when additional acid or base is introduced into the solution because the added acid reacts with the conjugate base, while added base reacts with the existing acid or the acid's dissociated protons. Bodily fluids contain multiple buffers, but the proportions of their acid form to their conjugate base form are all related by way of the shared hydrogen ion concentration of the fluid as

$$\begin{aligned} [\text{H}^+] &= K'_1 \times \frac{[\text{HA}_1]}{[\text{A}_1^-]} = K'_2 \times \frac{[\text{HA}_2]}{[\text{A}_2^-]} = K'_3 \times \frac{[\text{HA}_3]}{[\text{A}_3^-]} \\ &= \dots K'_n \times \frac{[\text{HA}_n]}{[\text{A}_n^-]} \end{aligned} \quad (28-4)$$

Thus, only one buffer pair needs to be considered to describe the system in terms of $[\text{H}^+]$ or pH. Carbonic acid and its conjugate base (bicarbonate) are selected as the representative buffer pair because of the ability of carbonic acid to dissociate to form carbon dioxide, the body's ability to excrete large amounts of carbon dioxide by way of the lungs, and ready availability of suitable assay methods.

In the presence of carbonic anhydrase, the reversible dissociation of carbonic acid to carbon dioxide occurs rapidly and in accordance with the principle of chemical mass action as

Following the general form of equation (28-2), carbonic acid can also form ionic dissociation products, a hydrogen cation and bicarbonate anion, as

Combining equations (28-5) and (28-6) yields²

Assuming equilibrium conditions, and substituting the carbonic acid dissociation reaction in equation (28-6) into the general form given in equation (28-3), yields³

$$K' = \frac{[H^+] \times [HCO_3^-]}{[H_2CO_3]} \text{ or, by re-arrangement:}$$

$$[H^+] = K' \times \frac{[H_2CO_3]}{[HCO_3^-]} \quad (28-8)$$

K' for this reaction can be empirically demonstrated to be 7.9×10^{-7} . Applying the negative logarithm function, and using analogous symbolism as employed by equation (28-1), yields a more convenient form for the constant, pK' , equal to approximately 6.1.⁴ The stoichiometric relationship shown in equation (28-5) allows substitution of CO_2 for carbonic acid as

$$[H^+] = K' \times \frac{[CO_2]}{[HCO_3^-]} \quad (28-9)$$

Molar concentration units of carbon dioxide are related to clinically familiar gas tension units by way of the gas's solubility coefficient, α (0.03 mmol/L per torr at 37°C), as

$$[CO_2] = \alpha \times P_{CO_2} \quad (28-10)$$

Substituting equation (28-10) into equation (28-9), supplying numerical approximations for the equilibrium and solubility constants, and using units of nanomoles per liter for $[H^+]$, millimoles per liter for $[HCO_3^-]$, and torr (equivalent to millimeters of mercury) for P_{CO_2} , yields

$$H^+ = 24 \times \frac{P_{CO_2}}{HCO_3^-} \quad (28-11)$$

which is known as the Henderson equation. Taking the negative logarithm of both sides of equation (28-9), and performing substitutions allowed by equations (28-1) and (28-10), yields^{2,4}

$$pH = pK' - \log \times \frac{\alpha \times P_{CO_2}}{[HCO_3^-]} \text{ or, by re-arrangement:}$$

$$pH = pK' + \log \frac{[HCO_3^-]}{\alpha \times P_{CO_2}} \quad (28-12)$$

which is known as the Henderson–Hasselbalch equation, basically a logarithmic form of the Henderson equation. Note that the K' term has been replaced by the symbol pK' , the negative logarithm of the modified equilibrium constant. Although equation (28-12) is based on equilibrium conditions, the relationship between the three acid-base variables pH, bicarbonate concentration, and carbon dioxide tension empirically prevail, even in unstable critically ill patients.⁴ This relationship also provides the basis for determining bicarbonate concentration in virtually all commercial blood gas analyzers, which utilize a hydrogen ion-selective glass electrode to determine pH and a Severinghaus electrode to determine P_{CO_2} , and then solve equation (28-12) for bicarbonate concentration. Either the Henderson equation or the Henderson–Hasselbalch equation can also be used in the clinical setting to check the internal consistency of the three acid-base variables obtained by blood gas analysis. This is accomplished by selecting any two of the reported variables, calculating the third variable, and comparing the calculated value to that reported. A significant discrepancy (after accounting for rounding to significant digits) signifies that one or more of the reported values is faulty, usually due to transcription error.

Multiphasic plasma or serum electrolyte profiles usually include measurements of sodium, potassium, chloride, and total carbon dioxide content (tCO_2). The latter analyte is often used interchangeably with bicarbonate concentration in clinical parlance. However, tCO_2 actually represents the combined molar concentrations of CO_2 and various acid-labile precursor forms of carbon dioxide. These include bicarbonate and several other chemical entities. Thus,

$$tCO_2 = HCO_3^- + CO_2 + CO_3^{2-} + H_2CO_3 + R-NH-COO^- \quad (28-13)$$

where $R-NH-COO^-$ represents labile carbamino compounds formed by combination of carbon dioxide with amine moieties of plasma proteins by

Quantitatively, however, the main constituents of tCO_2 are bicarbonate and dissolved CO_2 gas.

Thus, equation (28-13) can be closely approximated by eliminating the negligible terms, and substituting from equation (28-10), as³

$$t\text{CO}_2 = \text{HCO}_3^- + 0.03 \times \text{Pco}_2 \tag{28-15}$$

where total CO₂ content and bicarbonate concentration are given in millimoles per liter and Pco₂ is given in torr. Substituting average normal values for bicarbonate concentration (24.0 mmol/L) and arterial Pco₂ (Paco₂), 40 torr, yields a tCO₂ level of 25.2 mmol/L, which is only marginally higher than the bicarbonate concentration. However, in patients with marked hypercapnia, more significant discrepancies may be seen. For example, at a Paco₂ of 100 torr and bicarbonate concentration of 28.0 mmol/L, tCO₂ would equal 31.0 mmol/L.

SIMPLE ACID-BASE DISORDERS

A simple acid-base disorder is one in which there is either acidosis or alkalosis (Table 28–1), but not

TABLE 28–1 Basic nomenclature for describing primary acid-base disorders.

Acidemia	A state of abnormally low blood pH (< 7.36)
Alkalemia	A state of abnormally high blood pH (> 7.44)
Acidosis	A pathological process tending to acidify body fluids
Alkalosis	A pathological process tending to alkalinize body fluids
Metabolic	In describing an acid-base disorder, a disturbance caused by pathological gain or loss of acid (other than carbonic acid) or bicarbonate from the body
Respiratory	In describing an acid-base disorder, a disturbance caused by pathological gain or loss of carbonic acid (or CO ₂) from the body
Acute	In describing a primary respiratory acid-base disorder, a disturbance present from minutes to hours
Chronic	In describing a primary respiratory acid-base disorder, a disturbance present for more than about 2 days

both simultaneously, and this primary pathologic process is either of metabolic or respiratory origin, but not both. If sufficiently severe, a simple acid-base disturbance will always result in an abnormality in blood pH, that is, either alkalemia or acidemia. Thus, there are four cardinal acid-base disorders: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. The patterns of pH, Paco₂, and bicarbonate concentration representing these cardinal disturbances, uncomplicated by any superimposed acid-base disorder, have been observed in animal models in which the cardinal disturbance is imposed by an experimental procedure (eg, infusing an acid, such as HCl or lactic acid intravascularly, or manipulating minute ventilation in mechanically ventilated animals). These patterns have also been observed clinically in patients by independently surmising the particular acid-base process present and then examining the associated arterial blood gas assay results. Limited studies have also been performed in healthy human volunteers. The next four sections explain the patterns observed in these simple cardinal disorders, delineate the associated quantitative relationship between blood gas variables, list the differential diagnosis (ie, the underlying causes) of each cardinal disorder, and provide some simple methods for narrowing the differential diagnosis.

Metabolic Acidosis

From equation (28-7), it can be seen that loss of bicarbonate from the body, for example, from diarrhea, will result in formation of excessive hydrogen ion concentration by the principle of chemical mass action. On the other hand, addition of acid, either exogenous or generated by pathophysiologic metabolic processes, can directly increase hydrogen ion concentration and therefore lower pH. Also, equation (28-7) shows that addition of acid (H⁺) to body fluids generates carbon dioxide above and beyond the amount would be produced by normal physiologic mechanisms. Blood pH is expected to decrease from the added hydrogen ions that have not reacted with bicarbonate, and bicarbonate concentration will decrease from the hydrogen ions that combine with bicarbonate to form carbon dioxide. To prevent hypercapnia, the body has a built-in reflexive mechanism for dealing with this increased

CO₂ generation, namely, hyperventilation mediated through the brainstem at the level of the medulla. The afferent limb of this physiologic reflex reacts to the fall in pH to neurogenically effect hyperventilation. The increase in ventilation does not simply suffice to maintain baseline PaCO₂, but rather it lowers PaCO₂ below the normal range to a degree that is proportional to the extent of the metabolic acidosis. Empiric analysis of this proportionality in humans has been found to be linear, and can be represented by⁵

$$\text{Expected PaCO}_2 = 1.5 \times \text{HCO}_3^- + 8 \pm 2 \quad (28-16)$$

where HCO₃⁻ is the patient's observed bicarbonate concentration (in millimoles per liter), and expected PaCO₂ is the arterial carbon dioxide gas tension (in torr) that occurs statistically (ie, on average) in uncomplicated metabolic acidosis of a severity level corresponding to the observed bicarbonate concentration in the patient at hand.

Equation (28-16) follows the general form of a linear equation: $y = mx + b$, where m represents the slope of the linear equation when graphed on Cartesian coordinates with the X-axis representing HCO₃⁻ concentration and the Y-axis representing PaCO₂, and b represents the point of interception of the line along the Y-axis. The slope, given above by the factor 1.5 in equation (28-16), has been shown in some studies to be closer to 1.2.⁶ The term ± 2 is appended to represent the 95% confidence interval derived from empiric data. If simple (ie, uncomplicated by another primary acid-base disorder) metabolic acidosis is present, substituting the patient's bicarbonate concentration into equation (28-16) and finding the patient's PaCO₂ to be within the expected range derived from solving the equation, would signify that the patient's arterial blood gas findings are consistent with metabolic acidosis. A PaCO₂ value lying outside this range implies that metabolic acidosis either is not present, is incompletely developed, or is present in combination with some other cardinal acid-base disturbance. The latter situation would constitute a mixed acid-base disturbance.

Table 28–2 provides a differential diagnosis for metabolic acidosis. A classic method for narrowing this differential diagnosis is to use the results of a

basic multiphasic serum (or plasma) electrolyte panel to arrive at the anion gap by⁷⁻⁹

$$\text{Serum anion gap} = \text{Na}^+ - \text{Cl}^- - \text{tCO}_2 \quad (28-17)$$

where each analyte concentration is expressed in units of millimoles (or milliequivalents) per liter. The normal range for the serum anion gap varies among clinical chemistry laboratories, and has declined somewhat following the adoption of contemporary assay methods, but for some laboratories, it is 12 ± 4 mEq/L. Values exceeding the upper normal limit imply that an anion, other than chloride or bicarbonate, is present at pathological concentrations. The cause of abnormally high anion gap values, particularly if the degree of elevation is not subtle, of en can be confirmed, in whole or in part, by measurement of the culpable anion; for example, lactate if the cause is lactic acidosis, or β -hydroxybutyrate if the cause is ketoacidosis. Assays for some organic anions that can increase the anion gap, for example, glycolate in ethylene glycol poisoning as well as some inorganic anions, for example, sulfate accumulation in chronic renal failure, are not commonly available; however, information from the patient's medical history, physical examination, and ancillary laboratory assays can of en corroborate the specific diagnosis in these cases.

If the anion gap is normal, the cause of the metabolic acidosis is basically either loss of bicarbonate from the body or an etiology that does not involve excessive production of an organic acid. In cases of metabolic acidosis where the serum anion gap is not elevated, clinical information coupled with other simple laboratory tests can of en facilitate delineation of the cause.^{10,11} In cases of mild metabolic acidosis due to organic anion accumulation, the corresponding mild perturbation in the anion gap may not be sufficient to increase the gap above the upper normal limit. Similarly, a low baseline serum anion gap, as can occur in marked hypoalbuminemia, can have the same effect.⁸ The latter phenomenon can be taken into account by measuring serum albumin and recognizing that for every 1 g/dL decrease in serum albumin concentration, the serum anion gap decreases by about 2.4 mEq/L, on average.¹²

The serum osmole gap, of en used as a screening test when methanol or ethylene glycol intoxication

TABLE 28–2 Etiologies of metabolic acidosis classified by typical serum anion gap association.

Elevated Serum Anion Gap	Normal Serum Anion Gap
Chronic Renal Failure Lactic Acidosis Type A: due to tissue hypoxia or shock Type B1: due to certain disease states, but ostensibly not due to tissue hypoxia or hypoperfusion (eg, thiamine deficiency and some neoplasms) Type B2: due to certain drugs or toxins (eg, cyanide, metformin, propylene glycol, and nucleoside reverse transcriptase inhibitors) Type B3: congenital forms* (eg, glycogen storage disease type I and hereditary fructose intolerance) Ketoacidosis Diabetic ketoacidosis Starvation ketoacidosis Alcoholic ketoacidosis Infantile forms* (eg, succinyl CoA:3-ke-toacid CoA transferase deficiency) Intoxications Methanol or ethylene glycol poisoning Salicylate overdose Drug-induced pyroglutamic acidosis (eg, secondary to acetaminophen) Paraldehyde intoxication Other Congenital Organic Acidoses* including those which do not necessarily manifest as ketoacidosis or lactic acidosis (eg, 3-hydroxy-3-methylglutaryl-CoA lyase deficiency and maple syrup urine disease)	Gastrointestinal Related Diarrhea (some forms, especially small bowel secretory causes) Ileostomy drainage Enterocutaneous fistula Pancreatic or biliary drainage Some rectal villous adenomas Kidney Related Acute kidney injury Renal tubular acidosis (types I, II, and IV) Other tubulointerstitial renal disorders Ureterosigmoidostomy Ileal loop bladder Endocrine Related Diabetic ketoacidosis (mainly in recovery phase) Adrenal insufficiency Primary hypoaldosteronism Pseudohypoaldosteronism (types I and II) Hyporeninemic hypoaldosteronism Respiratory Related Posthypocapnia Toluene-containing glue inhalation Pharmacotherapy Related Excessive volumes of normal saline (ie, dilutional acidosis) Carbonic anhydrase inhibitors (eg, acetazolamide) Cationic amino acids (total parenteral nutrition infusions with insufficient organic anion additive) Hydrochloric acid administration NH ₄ Cl administration Arginine HCl administration

*Infantile organic acidosis due to inborn errors of metabolism.

is suspected, is another simple derived laboratory-based expression that can be helpful in the differential diagnosis of metabolic acidosis when either of these poisonings is suspected.¹³ The osmole gap can be elevated after methanol or ethylene glycol ingestion even before the metabolic acidosis develops. As methanol is metabolized to formate, or ethylene glycol is metabolized to glycolate, both of which are acid anions, the serum osmole gap declines, the serum anion gap rises, and metabolic acidosis evolves.¹⁴ The osmole gap is the difference between serum osmolality determined by freezing point depression osmometry (Osm_{fp}) and serum osmolality estimated from routinely available clinical chemistry testing (Osm_{est}), expressed as

$$\text{Serum osmole gap} = Osm_{fp} - Osm_{est} \quad (28-18)$$

Osm_{est} is calculated from simultaneous measurements of the main osmotically active constituents of normal plasma: sodium, urea nitrogen (BUN), and glucose, along with ethanol, if applicable, by:

$$Osm_{est} = 2 \times Na^{+} + BUN/2.8 + Glucose/18 + Ethanol/4.6 \quad (28-19)$$

where Na^{+} is expressed in millimoles per liter and the other serum assay results are expressed in milligrams per deciliter. The sodium concentration is doubled to account for osmotically active attendant anions that balance the positive charges of the sodium ions. The divisors in the other terms are derived from their respective molecular weights and convert their concentration units to millimoles (equivalent to milliosmoles) per liter. An elevated

osmole gap (>15 mOsm/kg H_2O or so) suggests the presence of occult osmoles, such as methanol or ethylene glycol molecules present in the sample and contributing to total osmolality.¹³ Other potential causes of an elevated serum osmole gap include ethanol intoxication (if the ethanol term is deleted from equation [28-19]), ketoacidosis, and severe degrees of circulatory shock.^{9,13}

Metabolic Alkalosis

Addition of bicarbonate or loss of hydrogen ions from the body elevates extracellular bicarbonate concentration, decreases hydrogen ion concentration, and correspondingly increases pH. As in metabolic acidosis, there is normally an associated reflexive change in pulmonary minute ventilation, but in this case manifesting as hypoventilation and resulting in CO_2 retention. The resulting hypercapnia does not represent respiratory dysfunction, but is an expected physiologic response to the metabolic alkalosis. The proportional change in ventilation, as manifested by $PaCO_2$, is related to the degree of metabolic alkalosis as expressed by the plasma bicarbonate concentration. One empirically derived equation describing this relationship is

$$\text{Expected } PaCO_2 = 0.9 \times HCO_3^- + 15 \quad (28-20)$$

The slope, given above as 0.9, has been shown in some studies to be closer to 0.7.⁶ Greater variability in this relationship has been observed compared to that seen in metabolic acidosis. Nevertheless, arterial blood gas values that approximate this relationship are consistent with simple metabolic alkalosis.

Once the diagnosis of metabolic alkalosis is established, the range of possible mechanisms or etiologies is considered (Table 28-3). As with metabolic acidosis, the applicable etiology is often apparent from information available through the medical history and physical examination.^{11,15} Gastric fluid loss, diuretic use, and extracellular volume contraction are among the most common causes. Excess alkali intake (< 10 mEq/kg) is excreted rapidly in most patients with normal renal function. However, exogenous alkali administration can lead to alkalosis in patients with compromised renal function, low chloride intake, or mineralocorticoid excess.¹⁶ Sources of exogenous alkali include oral or

TABLE 28-3 Etiologies of metabolic alkalosis classified by expected urine chloride concentration or excretion.

High (or normal) Urine Chloride (> 20 mEq/L)

Active diuretic use or abuse
Severe potassium depletion
Severe magnesium depletion
Chronic diarrhea (colonic origin, chiefly)
Chronic laxative abuse
Primary aldosteronism
Cushing syndrome
Apparent mineralocorticoid excess syndrome
Renal artery stenosis
Accelerated hypertension
Bartter syndrome
Gitelman syndrome
Liddle syndrome
Therapeutic corticosteroid use
Renin-secreting tumor
Licorice abuse
Carbenoxolone use
Refeeding alkalosis (normal NaCl intake)
Alkali ingestion or treatment (normal Cl^- intake and normal circulating volume, or nonoliguric renal failure)
Nonabsorbable antacids plus sodium polystyrene sulfonate
Milk-alkali syndrome

Low Urine Chloride (< 20 mEq/L)

Vomiting or nasogastric suction
Some colonic villous adenomas
Congenital chloridorrhea
Cystic fibrosis
Recently discontinued diuretic treatment
Extracellular volume depletion in general (ie, contraction alkalosis)
Chloride-deficient diet (eg, soybean and protein-based infant formula diet)
Alkali ingestion or treatment (low Cl^- intake and low circulating volume)
Acute correction of chronic hypercapnia
Refeeding alkalosis (in the face of low NaCl intake)
Nonreabsorbable anion (eg, high-dose penicillin or carbenicillin) in the face of extracellular volume contraction

parenteral bicarbonate (including oral baking soda or overtreatment with intravenous $NaHCO_3$), acetate (eg, in parenteral nutrition formulas or dialysate solutions), citrate (including secondary to multiple blood transfusions), lactate (including Ringer's lactate solutions), and gluconate salts (found, eg, in certain proprietary intravenous balanced salt solutions), or $CaCO_3$ (eg, in oral calcium supplements).

In cases when the etiology is not straightforward, a simple laboratory test, urine chloride measurement, can sometimes be helpful. Low urine chloride concentration (< 20 mmol/L), commonly points to gastric fluid losses (by vomiting or gastric suction), recently discontinued diuretic therapy, or a posthypercapnic state. The latter occurs commonly in patients with chronic carbon dioxide retention due to chronic obstructive pulmonary disease who are placed on mechanical ventilation with resultant rapid lowering of Paco_2 . High urine chloride concentration (> 20 mmol/L), on the other hand, points to a renal mechanism that involves chloride wasting with retention of the alternative anion bicarbonate. Common causes of chloride wasting in the intensive care unit setting are active diuretic administration and corticosteroid therapy. The urine chloride concentration also has therapeutic implications. Low urine chloride concentrations in the face of metabolic alkalosis are often readily corrected by simply supplying chloride in the form of ample sodium chloride-containing intravenous fluids. Patients with high urine chloride levels, for example, mediated by excessive mineralocorticoid activity, are resistant to therapy with chloride-containing parenteral fluid administration because the administered chloride load is excreted without correction of the alkalosis. Note that some patients with chloride-resistant forms of metabolic alkalosis may not manifest high urine chloride levels if they have been deprived of dietary or parenteral chloride.

Respiratory Acidosis

Acute hypoventilation in an otherwise normal subject results in decreased elimination of carbon dioxide, with a resultant rise in Paco_2 . Accompanying this rise is an immediate concomitant rise in the plasma bicarbonate level. This rapid rise in bicarbonate concentration is not mediated by renal mechanisms, but rather by the principle of chemical mass action affecting equation (28-7), shifting accumulated CO_2 leftward to form bicarbonate. Controlled and observational studies have demonstrated that the average rise in bicarbonate concentration (here measured in millimoles per liter) is approximately one-tenth the increase in arterial CO_2 tension (measured in torr), that is,^{2,6,17}

$$\text{Expected } \Delta \text{HCO}_3^- \approx 0.1 \times \Delta \text{Paco}_2 \quad (28-21)$$

When a hypercapnic patient's arterial blood gas values (Paco_2 tension and bicarbonate concentration) conform to equation (28-21) by comparison to known or assumed baseline (prehypercapnic) values, the results are consistent with simple acute respiratory acidosis.

The kidney normally reclaims bicarbonate filtered at the glomerulus by secreting hydrogen ions into the renal tubular lumen. The reaction between bicarbonate and hydrogen ions forms CO_2 by equation (28-7), and the CO_2 is readily absorbed from the tubules into the bloodstream where equation (28-7) then can operate in reverse, thus effectively resulting in bicarbonate reabsorption.² In sustained hypercapnia, the kidney normally responds by gradually increasing tubular hydrogen ion secretion, thereby enhancing bicarbonate reabsorption, adding to the bicarbonate-elevation effect given by equation (28-21). This renal effect on plasma bicarbonate concentration takes several days to fully evolve and is proportional to the degree of prevailing hypercapnia. Although the relationship is not precisely linear, the combined mass action and renal effects of chronic hypercapnia on bicarbonate concentration can be approximated by^{2,6}:

$$\text{Expected } \Delta \text{HCO}_3^- \approx 0.35 \times \Delta \text{Paco}_2 \quad (28-22)$$

When the patient's arterial blood gas values yield a plasma bicarbonate concentration that approximately conforms to that given by equation (28-22), the results are consistent with simple chronic respiratory acidosis. Patients having a bicarbonate concentration intermediate between the values obtained using equations (28-21) and (28-22) either have an intermediate degree of chronicity with respect to their hypercapnia, or have a mixed acid-base disturbance (see the final section).

Etiologies of hypercapnia can be divided into primary pulmonary derangements, primary neurological abnormalities, and metabolically mediated causes, with the latter potentially including drug or toxin-mediated causes (Table 28-4). The patient's medical history, physical examination, chest imaging studies and, where necessary, other investigations will assist in narrowing the differential diagnosis and arriving at the reason for respiratory acidosis.

TABLE 28–4 Etiologies of respiratory acidosis.

Pulmonary Disorders

Chronic obstructive lung disease
 Status asthmaticus
 Severe pneumonia
 Aspiration pneumonitis
 Acute respiratory distress syndrome
 Cardiogenic pulmonary edema (severe)
 Smoke inhalation
 Pneumothorax or hemothorax
 Thoracic skeletal disorders (eg, kyphoscoliosis, rib fractures, and flail chest)
 Extrathoracic restrictive processes (eg, obesity, ascites, and abdominal compartment syndrome)
 Mechanical ventilation with excessive deadspace
 Incorrect mechanical ventilation settings or ventilator malfunction
 Upper airway obstruction (eg, laryngospasm, airway tumor or foreign body, and obstructive sleep apnea)

Neurologic Illness or Injury

Traumatic brain injury
 Spinal cord injury
 Cerebrovascular accident
 Intracranial hemorrhage
 Brain tumor
 Intracranial hypertension
 Central nervous system infection
 Guillain–Barré syndrome
 Poliomyelitis
 Amyotrophic lateral sclerosis
 Obesity hypoventilation syndrome

Muscle and Neuromuscular Disorders

Myasthenia gravis
 Muscular dystrophy
 Polymyositis

Metabolic Disorders

Myxedema coma
 Severe hypokalemia
 Thyrotoxic hypokalemic periodic paralysis
 Familial hypokalemic periodic paralysis
 Severe hyperkalemia (rare)

Drug and Toxin Related

Sedative hypnotic drugs (eg, benzodiazepines, barbiturates, and propofol)
 General anesthetic (eg, halothane and other volatile anesthetics; nitrous oxide)
 Opioids (eg, morphine, heroin, hydromorphone, oxycodone, and fentanyl)
 Succinylcholine
 Nondepolarizing neuromuscular blocking drugs (eg, pancuronium, vecuronium, and atracurium)
 Reversible carbamate cholinesterase inhibitor overdose (eg, physostigmine and pyridostigmine)
 Organophosphate insecticide poisoning (eg, malathion and diazinon)
 Military nerve agents (eg, sarin, soman, and VX)
 Sodium bicarbonate administration in the face of ventilatory limitation
 Botulism
 Tetrodotoxin poisoning (eg, from puffer fish ingestion)

Respiratory Alkalosis

Acute hyperventilation in an otherwise normal subject results in increased elimination of carbon dioxide and therefore a fall in P_{aCO_2} . Accompanying this fall is an immediate concomitant decrease in plasma bicarbonate concentration. The rapid fall in bicarbonate is not mediated by renal mechanisms, but rather by the principle of chemical mass action affecting equation (28-7), causing a rightward shift in the reaction sequence to partially fill the void left by the expired CO_2 . Human observational studies have shown that the fall in bicarbonate concentration (measured in millimoles per liter) is approximately two-tenths the decrease in arterial CO_2 tension (measured in torr), that is,⁶

$$\text{Expected } \Delta HCO_3^- \approx 0.2 \times \Delta P_{aCO_2} \quad (28-23)$$

Arterial blood gas values showing hypocapnia and decreased plasma bicarbonate concentrations that approximate those given by equation (28-23) are consistent with simple acute respiratory alkalosis.

As described earlier, the kidney normally regulates bicarbonate reabsorption by adjusting hydrogen ion secretion into the renal tubular lumen. Sustained hypocapnia downregulates this hydrogen ion secretion, resulting in less reclaimed bicarbonate and thus enhancing bicarbonate excretion, adding to the bicarbonate lowering effect accounted for by equation (28-23). The added renal effect on bicarbonate concentration takes several days to fully evolve and is proportional to the degree of prevailing hypocapnia, as given by^{6,18}

$$\text{Expected } \Delta HCO_3^- \approx 0.4 \times \Delta P_{aCO_2} \quad (28-24)$$

However, this proportionality, representing the combined mass action and renal bicarbonate wasting effects of hypocapnia on plasma bicarbonate concentration, eventually reaches a limit such that further degrees of hypocapnia have little additional effect on the plasma bicarbonate level. Thus, plasma HCO_3^- concentrations much less than 17 mmol/L are not commonly observed in simple chronic respiratory alkalosis. Within this limit, arterial blood gas results that show hypocapnia and plasma bicarbonate concentrations that conform to that given by

equation (28-24) are consistent with simple chronic respiratory alkalosis. Patients having a bicarbonate concentration intermediate between the values obtained by equations (28-23) and (28-24) either have an intermediate degree of chronicity to their hypocapnia, or have a mixed acid-base disturbance (see the following section).

Etiologies of hypocapnia can be classified according to whether the primary disorder is pulmonary, neurological, metabolic, or a drug or toxin-mediated cause (Table 28–5). The patient’s medical history, physical examination, chest imaging studies and, where necessary, other investigations will assist in narrowing the differential diagnosis and arriving at the reason for respiratory acidosis.

TABLE 28–5 Etiologies of respiratory alkalosis.

Pulmonary Disorders
Asthma
Pneumonia
Pulmonary edema (mild to moderate)
Interstitial lung disease
Pulmonary embolism
Mechanical ventilation
High-altitude hypoxemia
Ventilation-perfusion mismatch
Intrapulmonary shunting
Other causes of hypoxemia
Neurological Disorders
Traumatic brain injury
Central nervous system infection

Nicotine intoxication
Progesterone administration
Exogenous catecholamines
Stimulant drug overdose (eg, cocaine, amphetamine)

MIXED ACID-BASE DISORDERS

Whereas simple acid-base disturbances involve a single primary underlying causative mechanism, either metabolic or respiratory, mixed acid-base disorders involve more than one cardinal acid-base derangement simultaneously. Co-occurrence of two or three of the cardinal acid-base disorders is not uncommon in critically ill patients and frequently complicates interpretation of arterial blood gas determinations in the intensive care unit setting.

The data used to derive the empiric formulas given for the cardinal acid-base disorder in the preceding sections have also been used to generate statistical confidence limits for each disorder. These confidence bands are approximated graphically in Figure 28–1, a plot of $Paco_2$ versus bicarbonate concentration.^{2,5,6,17,19} According to equation (28-12), a given $Paco_2$ and bicarbonate concentration defines a specific pH; therefore, lines of equal pH can be superimposed on the graph (the diagonal lines in Figure 28–1). The elliptical area near the center of the graph represents the 95% confidence area for the combined normal ranges for $Paco_2$ and bicarbonate concentration. The normal range for arterial blood pH (7.36-7.44) can be indirectly appreciated on the graph by interpolating between the diagonal lines. The dark bands represent confidence areas defining patterns of blood gas values that have been observed when the depicted cardinal acid-base disorder is present and is not complicated by another cardinal acid-base disturbance. For the respiratory disorders, both acute and chronic confidence bands are given. The overlap in the confidence bands near the center of the graph (at the outskirts of the normal confidence ellipse) illustrates that mild blood gas abnormalities can present greater diagnostic uncertainty compared to more severe abnormalities. Figure 28–1 also highlights the quantitative relationship between the three blood gas variables and shows that merely examining the directional changes in one or two of the variables, without considering the quantitative relationship between them, may not allow accurate identification of the cardinal disturbance. For example, finding that a patient has a low bicarbonate concentration does not allow one to distinguish whether the patient has metabolic acidosis or respiratory alkalosis. Similarly, knowing

FIGURE 28–1 Acid-base nomogram showing confidence bands for simple acid-base disturbances. Conversion factor: 1 torr = 0.13 kPa. (Adapted from Kruse JA. Acid-base interpretations. In: Prough DS, Traystman RJ, eds. *Critical Care. State of the Art. Vol. 14.* Mt. Prospect, Ill: Society of Critical Care Medicine; 1993:275-297. Used with permission.)

that a patient has a low bicarbonate level and low PaCO_2 does not discriminate between these two disturbances. Quantifying the relationship between the acid-base variables, however, often identifies which disorder is present.

When one of the cardinal respiratory disturbances is present, and the time course of the disorder is intermediate between an acute and a fully developed chronic disturbance, the blood gas values will lie between the acute and chronic respiratory bands. Analogously, when two cardinal disturbances are present simultaneously (eg, metabolic acidosis and respiratory alkalosis), the range of possible arterial blood gas values can lie anywhere between the confidence areas given for the two cardinal disorders in Figure 28–1. Thus, abnormal blood gas findings that do not fall within any of the confidence bands imply that a mixed disturbance is present. If there are two cardinal disorders present, the point representing the blood gas values will usually lie between the two bands representing the disorders.

Note that although blood gas results lying within a confidence band are consistent with the disorder represented by the band, it is still possible that a mixed disorder could be present. For example, a patient with simultaneous development of severe metabolic alkalosis (say, from protracted vomiting) and severe metabolic acidosis (say, from concomitant diabetic ketoacidosis) could present with arterial blood gas values that are within normal limits.⁸ Similarly, if metabolic acidosis and metabolic alkalosis are simultaneously present, but one of the disorders is more severe, the blood gas results may lie squarely within the confidence band of the more severe disorder, concealing the presence of the opposing metabolic disorder. Although this is a limitation of the method, consideration of information from the history and screening laboratory testing, particularly the serum anion gap in this case, will usually overcome the diagnostic challenge. As another example, a patient with metabolic acidosis and simultaneous chronic respiratory alkalosis

(Figure 28–1) may have blood gas values that are consistent with acute respiratory alkalosis. Again, the medical history and ancillary testing commonly surmount these limitations.

Each of the descriptive cardinal acid-base disturbances directly depicted in Figure 28–1 can be considered an acid-base diagnosis. Arriving at an acid-base diagnosis, however, is not an end in itself. Rather, the purpose of this identification process is to characterize the disorder so that a differential diagnosis can be formulated and the specific etiology then discerned. Pin-pointing the specific diagnosis requires additional information, available from the clinical context of the case, including the patient's medical, surgical, and medication use history, physical examination, and sometimes simple laboratory test results such as the serum potassium level, serum anion gap, or urine chloride concentration. Once the specific underlying diagnosis is ascertained, appropriate treatment can be implemented.

KEY POINTS

- 1 Malnutrition is associated with increased mortality and remains an underdiagnosed condition affecting critically ill patients. Timely and adequate screening is important to identify patients who are at risk.
- 2 Early enteral nutrition has been proven to be beneficial in ICU patients. Every effort should be made to initiate enteral nutrition within 48 hours of ICU admission unless clinically contraindicated.
- 3 Developing feeding protocols has been shown to increase nutrient administration
- and utilization of enteral nutrition in critically ill patients. Identifying procedures that focus on the use of promotility agents and avoiding unnecessary feeding interruptions is essential.
- 4 Inappropriate parenteral nutrition use has been associated with increased risk of infectious and metabolic complications. Delaying initiation of parenteral nutrition for at least 7 days may be prudent.

MALNUTRITION AND CRITICAL ILLNESS

An estimated 40% to 50% of patients admitted to the ICU are undernourished or at risk for malnutrition.¹ Malnutrition is known to impair tissue function, delay wound healing, prolong ventilator dependence, and increase length of hospital stay.^{2,3} During critical illness, metabolic changes can lead to hyperglycemia, increased energy expenditure, and protein catabolism. The cytokine-driven and hormone-mediated response to stress is not only vital in stabilizing organ function and preserving immune competency, but it may also contribute to the loss of body mass and development of malnutrition. Therefore, adequate nutrition should aim to reduce severity and duration of the catabolic phase and optimize nutritional status for recovery.

CLASSIFICATION AND SEVERITY OF ADULT MALNUTRITION

Adult malnutrition is poorly defined and frequently unrecognized, hence the incidence and prevalence are difficult to determine. Clinical terms, such as marasmus, kwashiorkor, and protein-calorie malnutrition have previously been used to identify malnutrition; however, the use of some of these terms is confusing and antiquated. They were originally meant to distinguish the different clinical features of acute malnutrition in children ([Table 29–1](#)).

While numerous tools for identifying and classifying malnutrition have been developed, their application has often led to further confusion and

TABLE 29–1 **Malnutrition definitions.**

Protein-calorie malnutrition: Malnutrition usually seen in infants and young children whose diets are deficient in both proteins and calories. Clinically, the condition may be precipitated by other factors, such as infection of intestinal parasites.
Kwashiorkor: A severe protein-deficiency type of malnutrition in children. It occurs after the child is weaned. The clinical signs are, at first, a vague type of lethargy, apathy, or irritability and later, failure to grow, mental deficiency, inanition, increased susceptibility to infections, edema, dermatitis, and liver enlargement. The hairs may have reddish color.
Marasmus: Emaciation and wasting in an infant due to malnutrition. Causes include caloric deficiency secondary to acute diseases, esp. diarrheal diseases of infancy, deficiency in nutritional composition, inadequate food intake, malabsorption, child abuse, failure-to-thrive syndrome, deficiency of vitamin D, or scurvy.

misdiagnoses. More recently, focus has shifted away from using prognostic indicators, such as protein stores, as they are not an accurate indicator of nutritional status. The Academy of Nutrition and Dietetics and the American Society for Parenteral and Enteral Nutrition (ASPEN) have developed standardized diagnostic criteria for defining and documenting adult malnutrition in the clinical setting. The consensus defined adult malnutrition in the context of acute illness or injury, chronic diseases or conditions, and starvation-related malnutrition. Since there is no single parameter for identifying malnutrition, presence of 2 or more of the following characteristics is recommended for the diagnosis: insufficient energy intake, weight loss, loss of muscle mass, loss of subcutaneous fat, localized or generalized fluid accumulation, and diminished functional status as measured by hand grip (Table 29–2).⁴

TABLE 29–2 **Diagnostic criteria for malnutrition. Patient must meet 2 or more characteristics for the diagnosis of malnutrition.**

Characteristic	Acute Illness/Injury-Related Malnutrition		Chronic Disease-Related Malnutrition		Social/Environmental-Related Malnutrition	
	Nonsevere	Severe	Nonsevere	Severe	Nonsevere	Severe
Energy intake	< 75% for > 7 days	≤ 50% for ≥ 5 days	< 75% for ≥ 1 month	≤ 75%/ ≥ 1 month	< 75% for ≥ 3 months	≤ 50% for ≥ 1 month
Weight loss	1%-2%/1 week 5%/1 month 7.5%/3 months	> 2%/1 week > 5%/1 week > 7.5%/3 months	5%/1 month 7.5%/3 months 10%/6 months 20%/1 year	> 5%/1 month > 7.5%/3 months > 10%/6 months > 20%/1 year	5%/1 month 7.5%/3 months 10%/6 months 20%/1 year	> 5%/1 month > 7.5%/3 months > 10%/6 months > 20%/1 year
Physical Findings						
Body fat	Mild depletion	Moderate depletion	Mild depletion	Severe depletion	Mild depletion	Severe depletion
Muscle mass	Mild depletion	Moderate depletion	Mild depletion	Severe depletion	Mild depletion	Severe depletion
Fluid accumulation	Mild	Moderate to severe	Mild	Severe	Mild	Severe
Grip strength	Not applicable	Not recommended in ICU	Not applicable	Reduced for age/gender	Not applicable	Reduced for age/gender

NUTRITION ASSESSMENT

The application of conventional risk and assessment tools is generally not practical in critically ill patients. Use of body weight (BW) as a marker of nutritional status can be problematic because of fluids shifts associated with critical illness. Markers of protein status, such as albumin and prealbumin levels are also of limited use, as they tend to be more reflective of acute phase response than a patient's nutritional status.⁵

A review of weight, caloric intake prior to ICU admission, and gastrointestinal tract function should be conducted prior to initiating any form of nutrition support.^{6,7} Risk assessment in critically ill patients should include evaluation of clinical status, length of time on mechanical ventilation, and severity and duration of stress response. Early and adequate nutrition support is important to avoid large cumulative energy deficits, which can lead to increased ventilator days and increased ICU length of stay (LOS).⁷ Avoiding overfeeding in critically ill patients is equally important, as excessive calories can result in hyperglycemia and increased carbon dioxide production, thus exacerbating respiratory insufficiency and prolonged weaning from the ventilator.

CALCULATING NEEDS

Measuring nutrient requirements is the first step in providing adequate nutrition. The use of an established amount of calories per kilogram has historically been applied when calculating energy needs. The most frequently used amount is 25 kcal/kg/day. When using calories per kilogram to determine energy needs, it is important to identify the appropriate weight. The patient's height should first be obtained, followed by calculation of an ideal BW (IBW) (Table 29–3). Once calculated, the IBW should then be compared to the admission dry

weight. In patients who weigh less than 90% of their IBW, practitioners should consider using the actual BW to calculate needs and avoid overfeeding, particularly in the early stages of critical illness.

Indirect calorimetry, which measures oxygen consumption and carbon dioxide production to calculate resting energy expenditure, remains the gold standard for estimating needs in the critically ill patient. However, its use is often not practical, due to the expense of the machines, lack of reimbursement, shortage of personnel trained in its use, and length of actual testing. Predictive equations offer another method for estimating calorie needs by using measurable data, including anthropometrics, to calculate estimated energy expenditure. Table 29–4 outlines equations developed for critically ill patients.

Identifying the appropriate method for estimating needs in critically ill overweight and obese patients can be challenging. Table 29–5 outlines the interpretations for BMI classifications. In patients defined with class I to III obesity (BMI > 30), calculating 22 to 25 kcal/kg of IBW has been recommended.^{6,7} Adjusted BW calculations should be used with caution as they may be unreliable. In 2013, the ASPEN published guidelines for hospitalized adult patients with obesity, recommending the Penn State University 2010 equation and the modified Penn State University equation for obese patients over 60 years of age. A 70% or greater accuracy was found using Penn State compared to other predictive equations.⁸

Validation studies have demonstrated improved accuracy with predictive equations, even though they are less accurate than indirect calorimetry. In the absence of indirect calorimetry, guidelines suggest using predictive equations or simple weight based equations (kcal/kg) for estimating calorie needs in critically ill patients.⁷ However, the use of predictive equations can be time consuming, and therefore, less appealing in the clinical setting.

TABLE 29–3 Formulas for determining IBW.

Females: IBW = 100 lbs for the first 5 ft of height, and an additional 5 lbs for each inch above

Males: IBW = 106 lbs for the first 5 ft of height, and an additional 6 lbs for each additional inch above

NUTRITION SUPPORT AND THERAPY

Enteral Nutrition

Enteral feeding is physiologic and the preferred route of providing nutrition in the ICU. In patients

who are unable to start oral diet, nutrition support should be initiated, preferably enteral feeding, if the gut is functional. In conditions where enteral nutrition is contraindicated, such as in the case of intestinal obstruction, severe ileus, high-output ileostomy, active gastrointestinal bleeding, or hemodynamic instability, and the patient requires non–per-orem

status for more than 7 days, parenteral nutrition (PN) should be considered. However, once these conditions resolve, enteral feeding should be started or resumed.

Enteral feeding maintains gut integrity and function, helps attenuate inflammatory responses, maintains gastrointestinal blood flow and peristalsis, and prevents bacterial translocation. Enteral nutrition should be initiated within the first 24 to 48 hours of ICU admission. In hemodynamically stable patients, providing enteral nutrition may reduce the incidence of infectious complications, reduce ICU and hospital mortality, and may be cost effective.^{9,10} ASPEN/SCCM guidelines support the early initiation of enteral feeds with advancement toward goal over the next 48 to 72 hours.^{6,7}

Enteral feeding is commonly provided via a nasogastric tube, orogastric tube, nasojejunal tube, or endoscopically or surgically inserted gastrostomy (G-tube) or jejunostomy (J-tube) tubes. In practice, gastric feeding is the preferred method

TABLE 29–5 BMI classifications.

BMI [Weight (kg)/Height (m ²)]	Classification
< 18.5	Underweight
18.5-24.9	Normal weight
25-29.9	Overweight
30-34.9	Obesity class I
35-39.9	Obesity class II
> 40	Obesity class III

for providing nutrition in the ICU because it is more physiological and easier to place than more distal enteral access devices. Intra-gastric feeds can be given either as a bolus or continuously via pump infusion. Impaired gastric emptying, which is a relatively common problem, may preclude the use of intra-gastric feeding. Known factors that predispose patients to develop impaired gastric emptying include drugs (sedatives, opioids, anticholinergics, and neuromuscular blocking agents), the presence of metabolic abnormalities (hypokalemia, acidosis, hypothyroidism, and long-standing diabetes), and the presence of anatomic abnormalities, infections, or muscle disease. Symptomatic patients with gastroparesis may benefit from decreasing doses of sedatives and opioid analgesics, or by adding prokinetic drugs, such as metoclopramide, erythromycin, or domperidone, which may help facilitate gastric motility. In severe cases of impaired gastric emptying, such as recurrent vomiting, persistently elevated gastric residual volumes, presence of gastric reflux refractory to medical treatment, or in the presence of severe acute pancreatitis,

postpyloric feeding may be favorable and should be considered.

Enteral Formulas

There are several enteral formulas designed for use in the ICU.¹¹ Generally, these formulas differ in their protein and fat content and are classified as standard (polymeric), specialized (disease-specific and immune-enhancing), semielemental (oligomeric), or elemental (monomeric).^{11,12} Standard or polymeric enteral formulas contain intact protein, complex carbohydrates, long-chain triglycerides, a balanced amount of micronutrients, and are usually less expensive than specialized formulas. The caloric density of a standard enteral formula can range from 1.0 to 2.0 kcal/mL. Calorie dense products are formulas that contain higher amounts of calories per milliliter and are intended for patients that require less volume of free water, such as in congestive heart failure or renal failure. They can also be used in patients who require nocturnal or bolus feedings to avoid large volumes of feeding being infused at higher rates. [Table 29–6](#) outlines various enteral formulas commonly used in the ICU. Some enteral

TABLE 29–6 Enteral formulas commonly used in the ICU.

Description	Concentration (kcal/mL)	Carbohydrate (%)	Protein (%)	Fat (%)	Free H ₂ O (%)
Semielemental, isotonic eg, Peptamen 1.0, Vital 1.0	1.0	51	16	33	84
Semielemental low CHO, high protein eg, Peptamen AF, Vital 1.2	1.2	35-36	25	39-40	81
Semielemental, concentrated eg, Peptamen 1.5, Vital 1.5	1.5	49	18	33	77
Elemental, low fat eg, Vivonex RTF	1	70	20	10	85
Intact, electrolyte restricted eg, Nepro, Novasource Renal	1.8-2.0	34-37	18	45-48	72-73
Intact, high fiber eg, Jevity 1.2, Fibersource	1.2	53	19	29	81
Intact, low carbohydrate eg, DiabetiSource AC, Glucerna 1.2	1.2	35-36	20	44-45	81-82

formulas contain fiber, which may help improve diarrhea; however, studies have revealed conflicting results.^{13,14} Guidelines suggest formulas free of soluble and insoluble fiber be used in critically ill patients that are at high risk for bowel ischemia or obstruction.⁷

Specialized enteral formulas are designed for patients with existing medical conditions that may require adjustment of calories, carbohydrate, protein, electrolytes, vitamins, and minerals. Formula selection in patients with renal disease can vary depending on the degree of renal function, the presence or absence of renal replacement therapy, and the patient's nutrient requirement. These patients require formulas that are low in water content, potassium, phosphorus, and magnesium. Patients receiving renal replacement therapy, hemodialysis, or continuous veno-venous hemofiltration have higher protein requirements of up to 2.5 g/kg/day and do not necessarily require fluid restriction from enteral feedings. In the absence of hyperkalemia, hyperphosphatemia, or hypermagnesemia, a standard, high-protein enteral formula should be used.

Enteral formulas that contain a lower amount of carbohydrates and higher fat content are intended for use in patients with diabetes mellitus. There is no significant difference in glycemic control, mortality, ICU LOS, or ventilator days when using diabetic formulas compared to standard formulas.¹⁵⁻¹⁸ However, some studies showed a trend toward lower infection rate and lower daily insulin requirements in patients receiving the diabetic formula.¹⁸

Hepatic formulas contain increased amounts of branched-chain amino acids, for example, valine, leucine, isoleucine, and reduced amounts of aromatic amino acids, such as phenylephrine, tyrosine, and tryptophan, purposely designed to reduce the neurological symptoms of hepatic encephalopathy. Evidence supporting the use of these formulas is limited and routine use of these branched-chain amino acid-enriched enteral formulas in patients with advanced liver disease, with or without hepatic encephalopathy, are currently not recommended.^{19,20}

Conflicting evidence limits the routine use of specialized formulas for patients with chronic obstructive pulmonary disease and acute respiratory distress syndrome (ARDS). The enteral formulas for patients with chronic obstructive pulmonary

disease, generally, have lower carbohydrate content which theoretically were created to limit carbon dioxide production and reduce ventilatory load. An enteral formula with modified lipid component containing borage and fish oils as well as high amounts of antioxidants, believed to modulate inflammatory response, is also available for use in patients with ARDS. Although previous studies have revealed some evidence of improvement in gas exchange, fewer ventilator days, and lower ICU LOS in patients receiving specialized ARDS formulas, a recent multicenter RCT found that the use of omega 3 fatty acids, linolenic acid, and antioxidant in patients with acute lung injury did not improve clinical outcome (ventilator-free days) and may be harmful.²¹⁻²³ Therefore, the routine use of these formulas in patients with ARDS should be discouraged.

Although known to be 4 times as costly compared to standard formulas, the use of semielemental and elemental enteral formulas has gained popularity in patients with severe uncontrolled diarrhea and malabsorptive states. Elemental formulas contain amino acids, glucose polymers, and lower amounts of long-chain triglycerides, and were developed mainly for better absorption in patients suffering from malabsorption. They are preferentially used in patients with pancreatitis to avoid exocrine pancreatic stimulation. Semielemental formulas contain hydrolyzed proteins, such as oligopeptides, dipeptides, and tripeptides, simple sugars, glucose polymers, starch, and medium chain triglycerides absorbed directly across the small intestinal mucosa into the portal vein in the absence of lipase or bile salts.¹¹ In clinical studies, both formulas were found to be nonsuperior to standard formulas in providing nutrition and nitrogen balance in patients with malabsorption, and therefore, should be reserved for patients who have failed previous attempts at providing enteral feeding with a standard formula.²⁴⁻²⁶

Determining Goal Rates

Once the patient's caloric requirement and appropriate enteral formula are chosen, it is important to determine the daily duration of feeding. In the ICU, a 24-hour continuous pump infusion of gastric feeding is commonly employed. [Table 29-7](#) shows an example for calculating the enteral goal rate.

TABLE 29–7 Enteral nutrition formula sample.

1. Use caloric estimate (predictive equations vs kcal/kg) to figure total calorie goal
2. Choose a tube feed (TF) formula
3. Divide goal calories by kcal/mL of formula to determine daily volume of formula (= 1200 mL)
4. Divide daily volume by number of hours TF to infuse to determine goal rate

Example:

1. **Caloric estimate: 1440 kcal**
- 2.

Description	Concentration (kcal/mL)	CHO (%)	Protein (%)	Fat (%)	Free H ₂ O (%)
Semielemental low CHO, high protein	1.2	36	25	39	81

5. 1600 kcal/1.2 kcal/mL = 1200 mL
6. 1200 mL/24 h = 50 mL/h

Risks and Complications of Enteral Nutrition

Commonly encountered problems with enteral feeding in the ICU include gastrointestinal complications, mechanical problems, and metabolic derangements. In a multicenter, prospective cohort study of 400 patients evaluating 3700 feeding days, gastrointestinal complications associated with enteral nutrition were found to occur in about 62.8% of cases. These complications included high gastric residuals (39%), constipation (15.7%), diarrhea (14.7%), abdominal distention (13.2%), vomiting (12.2%), and regurgitation (5.5%).²⁷ The occurrence of diarrhea in the ICU is very rarely related to enteral nutrition use alone. Once diarrhea occurs, the investigation should first focus on ruling out pathologic causes as a result of infection, inflammation, or secretory or osmotic mechanisms, which occur in many states of malabsorption. More commonly, diarrhea can be caused by various medications and so obtaining a good drug history is very important to avoid sending unnecessary tests. Drugs that are well known to cause diarrhea include laxatives, magnesium-containing antacids, antibiotics, colchicine, lactose or sorbitol based products, non-steroidal anti-inflammatory drugs, and prostaglandins. A common infectious cause of diarrhea in the ICU is pseudomembranous colitis caused by *Clostridium difficile* from prolonged use of antibiotics. Addressing the underlying cause is the first step in the management of diarrhea in the ICU, and once diarrhea is proven to be nonpathologic, adding medications such as bismuth salicylate, loperamide,

diphenoxylate/atropine, octreotide, or opium tincture may be practical. Changing the enteral feeds to a more elemental form may also be of potential benefit.

Feeding intolerance often results in withdrawal of enteral nutrition which translates into decreased nutrient intake, longer ICU LOS and higher mortality.²⁸ An association between 12-day caloric adequacy and 60-day hospital mortality found that as the amount of calories delivered increases and reaches at least 80% to 85% of prescribed calories, mortality decreases.^{7,29} Essentially, the fewer calories the patient is able to receive, the greater the mortality. These findings validate the importance of receiving adequate nutrition during critical illness and the importance of developing strategies that maximize the benefits and minimize the risk of enteral nutrition. Some strategies developed to optimize delivery of enteral nutrition in the ICU include elevating head of bed at least 30°, proactive use of prokinetic agents, use of small bowel feeding, and implementation of feeding protocols.³⁰

The occurrence of hyperglycemia in patients fed enterally is relatively rare as compared to patients receiving PN. In the ICU, hyperglycemia is mostly multifactorial, a result of a combination of factors commonly seen in the critical setting, eg, use of steroids, insulin resistance during critical illness, and presence of preexisting diabetes mellitus. Evaluating appropriate caloric requirements and correct administration rates as well as reducing inciting medications, and adding insulin, may be necessary

in addressing hyperglycemia. Currently, aiming at moderate glycemic control with a blood glucose (BG) target between 140 and 180 mg/dL in critically ill patients is beneficial over strict BG control of 81 to 108 mg/dL.³¹ Electrolytes should also be monitored as imbalances in sodium, potassium, and phosphorus may also occur in patients receiving enteral feedings.

Though relatively rare in commercially available enteral formulas, microbial contamination of enteral feeding decanted in feeding bags occurs and is usually related to poor hand-hygiene of health care providers.^{32,33} Commercially prepared enteral formulas are considered sterile until opened. In most clinical settings, implementing strict hand washing and routine change of feeding bags (every 24 hours) are practices employed to reduce the risks of contamination.

Mechanical problems associated with enteral nutrition are generally related to placement and maintenance of enteral access. Difficulties during initial placement of nasogastric tube or nasojejunal tube may result in nasopharyngeal irritation, esophageal irritation and bleeding, tube misplacement, or perforation of the esophagus, stomach, or lungs. At particular risk are patients who are agitated and fail to cooperate during the insertion process. The use of stiffer feeding tubes and stylets may also contribute to these problems. Previously placed temporary feeding tubes should also be monitored for possible migration, kinking, and occlusion, and replaced as needed. Long-term enteral access is also associated with formidable risk that occurs either during initial placement or maintenance of these feeding tubes. Commonly associated complications are abdominal pain, tube leakage, irritation, or infection around the insertion site, peritonitis, fistulas, tube clogging or occlusion, and dislodgment of the tube, collar, or button. Regular use of water flushes may reduce incidence of clogging or occlusion of feeding tubes.

Feeding Protocols in the ICU

Clinical evidence has shown that the use of enteral feeding protocols in the ICU may lead to an overall increase in the utilization of enteral nutrition and improvement in the delivery of enteral feedings to critically ill patients.^{34,35} Additionally, the use of protocols and algorithms in enteral feeding increases

use of promotility agents and decreases unnecessary feeding interruptions related to intolerance from high gastric residual volume.³⁵

Parenteral Nutrition

PN is intravenous nutrition designed to meet the needs of patients with a compromised GI tract or other conditions that preclude the delivery of enteral nutrition. While the appropriate use of PN may improve patient outcomes, inappropriate use has been associated with infectious complications, increased metabolic abnormalities, and higher medical costs.³⁶ Efforts to reduce the inappropriate use of PN highlight the importance of developing guidelines for initiating PN support, which are carried out by multidisciplinary nutrition support teams who specialize in its provision. Indications for PN include short bowel syndrome, high output enteric fistula, small bowel obstruction, paralytic ileus and intractable vomiting, diarrhea, or high ostomy output.³⁷ Additionally, patients undergoing major upper GI surgery, who are unable to be fed enterally, and are identified as being severely malnourished, have been shown to benefit from perioperative PN. Timing of PN initiation is a controversial topic, specifically in patients who are well nourished prior to ICU admission. In well-nourished patients, delaying PN initiation has been shown to improve outcomes.^{6,7,38} In patients identified as having poor nutritional status or severe malnutrition, early PN use should be considered if enteral nutrition is unable to meet a patient's needs.

PN can be administered via central or peripheral venous access. Total PN (TPN) requires central venous access, where the tip of the catheter lies in or close to the superior vena cava allowing for infusion of hypertonic formulations. TPN is intended for patients who require PN support for greater than 7 to 14 days; however, patients can be maintained on PN for extended periods of time, years in some cases.⁵

In patients who require long-term TPN, a peripherally inserted central catheter or a tunneled cuffed catheter is placed for long-term access. Peripheral PN utilizes a peripheral vessel for administration. It is generally designed for short-term use, as the osmolarity of the solution must be less than 800 to 900 mOsm/L to prevent thrombophlebitis.⁵ In the critically ill patient, peripheral PN is generally

not practical, as large fluid volumes (2.4-3.0 L) are often required to provide significant calories and protein.

Calculating Needs

Calculating nutrient needs for patients on PN support is similar to that of patients being fed enterally. Providing less than 30 kcal/kg is recommended to avoid overfeeding. As previously stated, 25 kcal/kg is frequently used.

Once the appropriate weight and calories per kilogram are determined, energy needs can be calculated, and divided among carbohydrate and lipids (non-protein calories). The use of nonprotein calories, particularly in PN, is designed to spare protein in order to preserve lean body mass. When dividing estimated energy needs among carbohydrate (dextrose), protein (AA) and fat (lipids), a 60%/40% or 70%/30% 50%/25%/25% ratio is often employed (Table 29-8). However, adjusting protein requirements may result in altered distributions.

The amount of protein provided is calculated according to the underlying condition. In the case of critical illness, 1.5 g protein/kg BW is generally appropriate. In patients with large wounds or pressure ulcers, additional protein is required. Obese patients may require more than 2 g protein/kg. Standard recommendations for estimating protein should be followed for patients with renal failure. Patients on mechanical renal replacement therapy, such as hemodialysis or continuous venovenous hemofiltration, have higher requirements (≥ 1.5 g/kg BW) due to losses, and protein needs should be adjusted accordingly.

If an institution is equipped with an on-site PN pharmacy, there is greater opportunity for customizing the formulations to meet individualized patient needs. Hospitals without a PN pharmacy on site rely on outside vendors to mix and deliver the formulas to the institution. Turnaround time may be extended in this case; however, more companies are providing these services and meeting the needs of institutions by customizing bags and making timely deliveries.

Fluid and electrolyte requirements in critically ill patients can vary depending on a number of factors, including preexisting medical conditions, presence of renal dysfunction, and overall clinical status. Communication with the ICU team on the addition

of fluids and electrolytes is imperative to ensure that PN solutions are consistent with the therapies being provided by the ICU team. No more than 154 mEq/L of sodium is generally provided. Infusing more than 10 mEq/h of potassium should be avoided, unless the patient is severely hypokalemic. Prescribers should proceed with caution when increasing amounts of calcium and phosphorus in the PN solution, and are encouraged to work closely with pharmacy to ensure that formulations are not at risk for developing precipitates. Daily review of lab values is recommended to ensure PN is addressing the constantly changing needs of the patient.³⁹

The inclusion of micronutrients in PN solutions is important to avoid the complications that can result from deficiencies. Standard additions of multivitamins and trace elements are generally included. If serum total bilirubin is more than 4 mg/dL, trace elements can be eliminated to avoid accumulating copper and manganese, which are excreted in bile. Other additives included in PN formulas are H₂ blockers, vitamin K, heparin, regular insulin, and carnitine which plays a role in the transport and metabolism of fat.⁴⁰

Risks and Complications of Parenteral Nutrition

The complications associated with PN infusion are generally divided into 3 categories: mechanical, infectious, and metabolic. The most common mechanical complication is catheter occlusion, which can be related to thrombotic and nonthrombotic sources. While catheter-related infections are not common, their occurrence can significantly affect morbidity, mortality, and LOS. Instituting guidelines and following the appropriate standards of care to reduce infectious complications improve outcomes and ensure safe delivery of PN support.^{5,40}

Hyperglycemia is among the most common metabolic complications of PN infusion. Considerable controversy surrounding optimal BG levels for ICU patients exist. In postoperative cardiac patients, improved outcomes have been observed when implementing measures to maintain tight glycemic control (80-110 mg/dL). However, in most critically ill populations, the complications that result from hypoglycemia can have far more significant consequences. Moderate glycemic control (BG between

Calculate Fat (Lipid) needs; remaining calories after AA and CHO are calculated Total kcals – AA kcals – CHO kcals = Lipid kcals Lipid kcals / 10 kcals/g = ____ g Lipid</p> <p>(CHO and fat ratio can be adjusted per medical condition, for example in patients with rising worsening liver failure and rising LFTs can consider higher %CHO and lower% Lipid)</p> <p>Example (using 60 kg BW): Total Calories: 1500 kcal</p> <p>1. Protein (AA): 60 kg x 1.5 g/kg = 90 g 90 g x 4 kcal/g = 360 kcal</p> <p>2. Carbohydrate (Dextrose): 1500 kcal × .5 = 750 kcal 750 kcal/3.4 kcal/g = 220 g</p> <p>3. Fat (Lipid): 1500 kcal – 750 kcal (from CHO) – 360 kcal (from Protein) = 390 kcal 390 kcal/10 kcal/g = 39 g (can be rounded to 40 g)</p> <p><u>Calculate fluid requirements:</u> Grams AA/CHO/Lipid divided by [concentration of solutions] = minimum volume (ml)</p> <p>Protein (AA): 10 - 15% concentration Carbohydrate (CHO): standard dextrose solution- 70% concentration Fat: (Intralipid): 30% concentration Add 150 ml for additives (vitamins, minerals, trace elements, etc)</p> <p>Example 90 g AA / 0.1 = 900 ml + 220 g dextrose / 0.7 = 314.2 ml + 40 g lipid / 0.3 = 133.3 ml + 150 ml (for additives) Total = 1497.5 ml</p>

140 and 180 mg/dL) helps avoid hypoglycemia and appears to be safer than strict control.^{6,7,31,36,41} Steps to avoid hyperglycemia in patients receiving PN support include avoiding glucose infusion rates that exceed 5 mg/kg/min, close monitoring of BG levels, and providing insulin coverage as indicated.

The addition of chromium in TPN, for presumed deficiency, may also be considered in patients with unexplained hyperglycemia. When initiating PN a reduced concentration (half-strength) is recommended to observe glycemic response and determine whether insulin therapy is required.

Hypoglycemia is often a result of excess insulin provided either directly in the PN formulation or subcutaneously. A patient who experiences hypoglycemic episodes during PN infusion can be treated with ampules of 50% dextrose or continuous infusion of 10% dextrose. The PN solution may also be discontinued until a reformulation is available. In patients receiving large doses of insulin, who no longer require PN infusion, a 1 to 2 hours taper of PN at half the prescribed rate is helpful in reducing the occurrence of rebound hypoglycemia.⁶

Hypertriglyceridemia results from excessive dextrose infusion or rapid infusion of intravenous fat emulsions (IVFE). It is recommended that IVFE in PN formulations should not exceed 1 g/kg/day. Serum triglycerides should also be obtained prior to advancing IVFE to goal, and monitored weekly for changes. An acceptable serum triglyceride level for patients on PN support is less than 400 mg/dL. Intravenous lipids are considered acceptable for patients with pancreatitis whose serum triglyceride levels are within normal limits.^{6,39}

PN-associated liver dysfunction (PNALD) refers to liver and biliary dysfunction associated with the initiation of PN support. The 3 hepatobiliary disorders associated with PN infusion are steatosis, cholestasis, and gallbladder sludge/stones. Steatosis generally occurs within 2 weeks of initiation of PN support and may be the result of excessive infusion of calories. Biliary obstruction or impaired biliary secretion can cause cholestasis. In patients who require long-term PN support, cholestasis can progress to cirrhosis and liver failure.

Decreased enteral stimulation and suppression of cholecystokinin as a result of PN infusion can increase the risk for gallbladder sludge/stones.⁴² Patients who are more at risk for developing PNALD include those with intestinal failure, or extensive bowel resection. In patients with suspected PNALD, it is important to avoid overfeeding, particularly of nonprotein calories, which can promote lipogenesis and inhibit lipolysis. Trials of enteral nutrition and ultimate discontinuation of PN should also be explored.^{6,7,43}

Patients who are PN dependent generally receive IVFE as their source of essential fatty acids. Essential fatty acid deficiency (EFAD) can present within 1 to 3 weeks of receiving IVFE-free formulations, and include dermatitis, alopecia,

thrombocytopenia, fatty liver, and anemia. To prevent EFAD, 50 g weekly, eg, 250 mL of 20% IVFE or 500 mL of 10% IVFE should be provided.⁵

REFEEDING SYNDROME

Refeeding syndrome occurs when nutrition is reintroduced following a period of severe nutritional deprivation. The rapid delivery of nutrients can lead to glycogen and protein synthesis and quick uptake of glucose and amino acids, resulting in hypokalemia, hypophosphatemia, hypomagnesemia, and symptoms of acute thiamine deficiency. If left untreated, consequences include cardiac failure and neurological complications. Refeeding syndrome occurs in roughly 50% of severely malnourished patients fed orally, enterally, or parenterally. For severely malnourished patients, nutrition should be initiated and steadily increased with close monitoring and aggressive repletion of electrolytes as indicated.⁴⁴

IMMUNONUTRITION

The practical use of immune enhancing products in critically ill patients is controversial. Conflicting results on the variable effects of pharmaconutrients, such as glutamine, arginine, omega 3 fatty acids, and selenium make it difficult to implement routine guidelines for their use. As more data emerge on the potential benefits of these immune modulating agents, more specific guidelines and recommendations for the appropriate dosing, timing, and duration may emerge.⁴⁵

Acute Kidney Injury and Failure

Pritul Patel, MD and Leila Hosseini, MD

KEY POINTS

- 1 Current concepts of AKI in sepsis indicate that systemic inflammation, microvascular dysregulation, and mitochondrial alteration, leading to cell death may be more important than global renal hypoperfusion.
- 2 Urine output and SCr are at best surrogate markers of renal function, but can be “normal” in the presence of renal dysfunction.
- 3 Recent studies have identified new biomarkers of renal injury that can diagnose AKI earlier than SCr, but these are still in the primary stages of clinical adoption.
- 4 Prevention of contrast-induced AKI focuses on the use of noniodinated contrast media, minimizing contrast-media volume, avoiding repeat exposure to contrast media, and expanding plasma volume before administration of contrast media.
- 5 The published literature suggests that periprocedural dialysis has no protective effect against CI-AKI.

INTRODUCTION

Acute kidney injury (AKI) is the sudden decline of renal function resulting in the retention of nitrogenous waste products and the inability to regulate electrolytes and extracellular volume. The development of AKI is associated with increased morbidity and mortality. These patients have an increased hospital length of stay and hospital readmissions, all of which translate into increasing resource utilization. The number of deaths resulting from AKI continues to increase even though the treatment of AKI and care of critically ill patients has improved. The reason for this increase in absolute mortality from AKI is twofold: the incidence of AKI is increasing and patients with AKI are older, with a greater number and severity of comorbid conditions.¹ Furthermore, we are pushing the boundaries in medicine; sicker patients who once were untreatable are now

undergoing more complex and invasive diagnostic and surgical procedures.

PATHOPHYSIOLOGY

Although the kidneys receive approximately 20% of the total cardiac output, they are still at very high risk for ischemic injury. This dichotomy is explained by the fact that most renal blood flow (80%-90%) is directed toward the renal cortex, where it passes through the glomerulus and is filtered.² The most metabolically active portion of the kidney, however, is not the cortex but the medulla, which is responsible for creating the osmotic gradient that serves to reabsorb water and concentrate urine. In order to maintain this osmotic gradient, blood flow to the medulla is kept low. In fact, the oxygen tension in the medulla is only approximately 10 mm Hg.² This lack

of luxury perfusion to a metabolically active portion of the kidney predisposes it to ischemic injury. Furthermore, the kidney concentrates toxins that the body is exposed to, thereby amplifying the exposure of renal cells to toxic substances.

The etiology of AKI is traditionally divided into prerenal, intrinsic renal, and postrenal. Prerenal azotemia occurs as a complication of decreased renal perfusion with preservation of the cellular architecture of the renal parenchyma. Direct injury to the kidneys results in renal azotemia, or intrinsic renal injury. Postrenal azotemia occurs as a result of obstruction of the urinary outflow tract. The overwhelming majority of AKI in critically ill patients is caused by sepsis, whose mechanism does not quite fit within any of the traditional categories of AKI. It was traditionally thought that sepsis-induced AKI was caused by renal hypoperfusion due to systemic hypotension and renal vasoconstriction, along with reperfusion injury to the kidneys. However, this theory has recently come into question. It is now thought that while ischemia may play a role, there are many other pathophysiologic mechanisms at work. Recent human and animal studies have shown that renal blood flow is preserved in sepsis. Current concepts of AKI in sepsis indicate that systemic inflammation, microvascular dysregulation, and mitochondrial alteration, leading to cell death may be more important than global renal hypoperfusion.³ This theory claims that sepsis induces an “inflammatory danger signal” that is initially adaptive and later becomes maladaptive, leading ultimately to, metabolic reprioritization of renal cells which favors cell adaptive processes (like maintenance of cell membrane potential and cell cycle arrest) at the expense of actual filtration of blood.³

Renal hypoperfusion is the hallmark of prerenal AKI. Renal hypoperfusion (resulting from prolonged hypotension, hemorrhage, abdominal compartment syndrome, low cardiac output states, or cirrhosis) is a common cause of prerenal AKI in the ICU. Medications that interfere with normal renal autoregulation (nonsteroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, angiotensin receptor blockers, cyclosporine, and tacrolimus) can precipitate AKI in patients with marginal renal perfusion. Prerenal azotemia

presents with decreased glomerular filtration rate (GFR) and little evidence of cellular damage in most cases. Therefore, the condition is usually completely reversible. Prolonged prerenal azotemia, however, can lead to evidence of cellular damage, usually in the form of acute tubular necrosis.

Intrarenal AKI has many causes and is best understood when classified by the location of the lesion: glomerulus, tubule, vasculature, or interstitium. Most intrarenal AKI in the ICU setting is due to acute tubular necrosis from prolonged hypotension, nephrotoxic medications, recent exposure to radiographic contrast agents; or interstitial nephritis from nephrotoxic medications, such as antibiotics. Glomerular and vascular causes of intrarenal AKI are more commonly causes of renal failure outside of the ICU.

Urinary indices can be helpful in distinguishing prerenal and renal azotemia in non-ICU settings. A fractional excretion of sodium (FE_{Na}) less than 1% is commonly used in the non-ICU setting to identify patients with prerenal AKI. However, in the ICU, where many patients receive diuretics, the FE_{Na} becomes unreliable and should not be routinely used as a diagnostic test. An elevated blood urea nitrogen (BUN)/creatinine ratio is also not necessarily indicative of prerenal AKI in ICU patients due to the lengthy list of comorbidities that may elevate the BUN/creatinine ratio in a euvolemic ICU patient (gastrointestinal hemorrhage, total parenteral nutrition, steroids, catabolic stress). Analysis of urinary sediment can be used to distinguish prerenal and intrarenal AKI, but these tests have limited use in an ICU setting. Generally, the microscopic examination of urine in patients with prerenal or postrenal AKI is normal. Red blood cell casts, protein, white blood cells or leukocyte casts, or hematuria suggest intrarenal causes of AKI.

Postrenal AKI occurs when there is bilateral or unilateral obstruction in urinary flow. This leads to an increase in intratubular pressure, eventually leading to a decrease in glomerular filtration pressure. Postrenal AKI is a very rare cause of AKI in the ICU, since most patients in the ICU have a urinary catheter. Obstruction of the urinary tract can be extrarenal or renal. Extrarenal causes include prostatic hypertrophy, and abdominal/retroperitoneal masses compressing the ureters. Intrarenal obstruction can

be caused by deposition of stones, crystals, clots, or tumors.

DEFINITION

The RIFLE (acronym stands for: risk, injury, failure, loss, and end-stage renal disease) criteria established a universal definition of AKI, facilitating communication among clinicians and researchers. The criteria include three severity grades (risk, injury, and failure), which are based on changes in serum creatinine and urine output, using the worst of each measure.⁴ The criteria also include two outcome criteria (loss and end-stage renal disease), which are based on the duration of the loss of kidney function.⁴ The RIFLE criteria have been validated with multiple trials showing that the severity of AKI, as defined by the RIFLE criteria, is associated with increased mortality.

The Acute Kidney Injury Network (AKIN) made modifications to the RIFLE criteria in order to take into account the importance of timing in kidney injury. Their diagnostic criteria for AKI include an abrupt (within 48 hours) reduction in

kidney function defined by an absolute increase in SCr of more than or equal to 0.3 mg/dL, a percentage increase in SCr of more than or equal to 50% (1.5-fold from baseline) or a reduction in urine output (less than 0.5 mL/kg/h for more than 6 hours).⁴ Their classification system involves a numbered system where stage 1 corresponds with RIFLE R, stage 2 with RIFLE I, and stage 3 with RIFLE F. Loss and end stage kidney disease were removed from the staging system (Table 30–1).

The AKIN and RIFLE criteria are useful measures of AKI, but are also fraught with limitations. Urine output and SCr are at best surrogate markers of renal function, but can be “normal” in the presence of renal dysfunction. The use of SCr can delay the diagnosis of renal injury and increases in SCr are only detected after a substantial reduction in GFR. In this sense, creatinine reflects renal injury that has already occurred. Creatinine is also affected by many factors other than renal dysfunction including muscle mass, catabolic state, rhabdomyolysis, dilutional effects, and drugs. Recent studies have identified new biomarkers of renal injury that can diagnose AKI earlier than SCr,

TABLE 30–1 Comparison of AKI staging criteria versus RIFLE staging criteria.⁴

AKI Staging		RIFLE	
Serum Creatinine	Urine Output (Common to Both)	Class	Serum Creatinine or GFR
Stage 1 Increase of more than or equal to 0.3 mg/dl ($\geq 26.5 \mu\text{mol/l}$) or increase to more than or equal to 150% to 200% (1.5- to 2-fold) from baseline	Less than 0.5 ml/kg/h for more than 6 hours	Risk	Increase in serum creatinine $\times 1.5$ or GFR decrease $> 25\%$
Stage 2 Increased to more than 200% to 300% (> 2 - to 3-fold) from baseline	Less than 0.5 ml/kg/h for more than 12 hours	Injury	Serum creatinine $\times 2$ or GFR decreased $> 50\%$
Stage 3 Increased to more than 300% (> 3 -fold) from baseline, or more than or equal to 4.0 mg/dl ($\geq 354 \mu\text{mol/l}$) with an acute increase of at least 0.5 mg/dl ($44 \mu\text{mol/l}$) or on RRT	Less than 0.3 ml/kg/h for 24 hours or anuria for 12 hours	Failure	Serum creatinine $\times 3$, or serum creatinine $> 4 \text{ mg/dl}$ ($> 354 \mu\text{mol/l}$) with an acute rise $> 0.5 \text{ mg/dl}$ ($> 44 \mu\text{mol/l}$) or GFR decreased $> 75\%$
		Loss	Persistent acute renal failure=complete loss of kidney function > 4 weeks
		End-stage kidney disease	ESRD > 3 months

but these are still in the primary stages of clinical adoption.

AKI RISK FACTORS

The risk of developing AKI is dependent on the interplay between a patient’s preexisting susceptibility to kidney injury combined with the duration of exposure to insults that result in AKI.⁴ Table 30–2 summarizes the most common risk factors and exposures leading to AKI.

AKI MANAGEMENT

There are some general underlying management strategies that are common to all types of AKI. The mainstay of AKI management relies on early diagnosis and prompt intervention to minimize injury to the kidneys. In addition, adjusting to renal doses of renally metabolized medications is crucial as is avoiding any additional exposure to nephrotoxic drugs.⁵

In general, hemodynamic management, assessment of volume status, and management of fluid administration become even more important once

renal function has deteriorated. Hypotension and decreased circulating volume can lead to hypoperfusion and ischemia of the kidneys; especially since injured kidneys lose the ability to autoregulate blood flow and become dependent on the mean arterial pressure to maintain perfusion. Conversely, overaggressive fluid resuscitation can lead to tissue edema, hypoxia, and heart failure, exacerbating poor perfusion to the kidneys. Positive fluid balance in AKI has been correlated with increased 60 days mortality in large multicenter studies.⁶ Strict hemodynamic monitoring and control of volume status in patients with AKI is critical and sometimes requires invasive cardiac monitoring or frequent bedside echocardiographic monitoring.

The type of fluid used for resuscitation in AKI and critically ill patients remains controversial. The Saline versus albumin fluid evaluation (SAFE) trial showed that albumin and crystalloids were equivalent in terms of renal outcomes.⁷ It is probably prudent to avoid volume resuscitation with hetastarch in patients with AKI as recent evidence points to increased renal injury and increased incidence of renal replacement therapy with the use of hetastarches.⁸ It is generally accepted that buffered salt solutions (such as lactated ringers, or Plasmalyte) may be the best agents for intravascular fluid resuscitation.⁴ Some studies indicate that normal saline administered in large quantities can cause hyperchloremia, leading to decreased renal perfusion and increased incidence of AKI and need for renal replacement therapy. There is also a trend towards a hyperchloremic metabolic acidosis, leading to hyperkalemia.⁹

Frequently, patients in the ICU have shock of various etiologies, and after adequate fluid resuscitation, the use of vasopressors is often necessary to maintain an adequate arterial blood pressure. A large randomized study comparing the use of dopamine to norepinephrine infusions in patients with septic shock found that there was no difference in mortality or renal function, but dopamine was associated with more adverse events.¹⁰ Both norepinephrine and vasopressin are suitable agents for the treatment of septic shock in patients that have been adequately volume resuscitated. Vasopressin has been gaining popularity because of some evidence that it may be superior to norepinephrine at reducing the progression of AKI, leading to less patients requiring RRT.¹¹ Finally, inotropes in conjunction with vasopressors

TABLE 30–2 Causes of AKI.⁴

Exposures	Susceptibilities
Sepsis	Dehydration or volume depletion
Critical illness	Advanced age
Circulatory shock	Female gender
Burns	Black race
Trauma	CKD
Cardiac surgery (especially with CPB)	Chronic diseases (heart, lung, liver)
Major noncardiac surgery	Diabetes mellitus
Nephrotoxic drugs	Cancer
Radiocontrast agents	Anemia
Poisonous plants and animals

also have a place in the treatment of hypotension due to cardiogenic shock as they help improve overall perfusion to all organs.

GLUCOSE MANAGEMENT IN AKI

Glycemic control among the critically ill is a controversial topic. Hyperglycemia and insulin resistance seem to be natural physiologic responses to critical illness, which occur in response to inflammatory mediators that are released during critical illness. Multiple studies have not shown any benefits of intensive insulin therapy and instead have shown an increased risk of hypoglycemia. The largest randomized trial of intensive glucose control in the ICU (NICE-SUGAR trial) failed to show a benefit in prevention of organ dysfunction, mortality, or bacteremia in patients with tight glucose control (81-108 mg/dL) compared to standard glucose control (140-180 mg/dL).¹² The KDIGO guidelines for the management of AKI suggest that critically ill patients should be treated with insulin for the prevention of severe hyperglycemia. Currently the blood glucose target supported by the majority of medical associations is 110 to 180 mg/dL.⁴

DOPAMINE, FENOLDOPAM, ATRIAL NATRIURETIC PEPTIDE, NESIRITIDE

Dopamine has been used in the past as prophylaxis against and treatment of renal failure in critically ill patients. Low-dose dopamine (1-3 mcg/kg/min) administered to healthy individuals results in renal afferent arteriole vasodilation, natriuresis, and increased GFR.¹³ However, in patients with AKI, low-dose dopamine has in fact been shown to increase renal vascular resistance.¹³ A large, randomized, placebo controlled, double-blinded study showed that dopamine had no renal protective effects.¹³ There is some evidence that shows that the use of dopamine in AKI can even cause harm. It has been linked with tachy-dysrhythmias, myocardial ischemia, decreased intestinal blood flow, and can suppress immune function. Therefore, the use of dopamine to prevent or treat AKI has been abandoned.⁴

A promising agent for the prevention and treatment of AKI involves the use of fenoldopam. Fenoldopam is a pure dopamine 1-type receptor agonist with no alpha- or beta-receptor properties that is currently only indicated for treatment of hypertension. It reduces systemic vascular resistance and increases renal blood flow. Fenoldopam has been shown in small trials to have a renal protective effect, preventing the development of AKI.¹⁴ While the data is promising, there are still no multicenter, highly powered, randomized controlled trials showing a clinically significant benefit of using fenoldopam in AKI. Furthermore, the hypotension that it causes is a significant side effect particularly in critically ill patients.

Atrial natriuretic peptide (ANP) is another potential therapy for the prevention and treatment of AKI. ANP is an amino acid that is released from the atrium in response to atrial stretch. It has diuretic, natriuretic, and renal vasodilatory activity, and can potentially increase GFR. There have been several negative studies concerning the use of ANP as prophylaxis against AKI.¹⁵ Therefore, until further research proves a benefit, ANP should not be used for treatment or prevention of AKI.

Nesiritide is a recombinant form of brain natriuretic peptide that has been approved by the Food and Drug Administration for use in decompensated heart failure.⁴ It may improve GFR, decrease rise in SCr, and improve urine output in patients, especially those with baseline renal insufficiency. In a pilot trial, nesiritide infusion started during and after cardiopulmonary bypass was shown to improve SCr values in patients with left ventricular dysfunction undergoing cardiac surgery.⁴ Nesiritide is not FDA approved for this indication.

DIURETICS

Patients with AKI are frequently administered diuretics, either before or after being diagnosed with AKI. According to one observational study, approximately 59% to 70% of patients with AKI were shown to have been administered a diuretic before the onset of RRT.¹⁶ There are multiple reasons for administering diuretics to a patient with AKI. Nonoliguric renal failure has a better prognosis than oliguric renal failure; therefore, many clinicians administer diuretics to convert oliguric renal failure

into nonoliguric renal failure. Diuretics can sometimes ameliorate fluid overload, commonly seen with AKI. Furthermore, some diuretics are thought to have renoprotective effects. However, improper diuretic use can lead to a decrease in intravascular volume, exacerbating prerenal insult to the kidneys.

Loop diuretics, such as furosemide, have a potentially renoprotective profile that may serve to protect the kidneys from AKI. They inhibit the Na^{2+} - K - 2Cl^{-} transporter in the ascending limb of the Loop of Henle. Inhibition of this active sodium transporter may decrease the oxygen demand of the renal tubule and protect the kidney against ischemia.¹⁷ Furosemide also increases the flow of urine in the renal tubules, helping to wash out ischemia-related necrotic debris blocking the tubules.¹⁷

A meta-analysis by Ho et al examined the effect of loop diuretics in AKI. They found that furosemide had no impact on hospital mortality, the requirement for RRT, number of dialysis sessions, or the incidence of oliguria. Furosemide was not effective for the prevention of AKI; it did not improve mortality in AKI and did not reduce the severity of AKI. Furosemide also did not decrease the duration of CRRT therapy and did not facilitate the return of renal function.¹⁸ However, furosemide does have a role for the management of hypervolemia, hyperkalemia, and hypercalcemia in AKI.⁴

Mannitol has been used to prevent AKI, however, most of the studies showing a beneficial effect of mannitol are underpowered, retrospective, and of poor quality.⁴ Mannitol may be beneficial when administered just prior to the arterial clamp removal in renal transplantation. In this setting, mannitol has been shown to decrease posttransplant AKI, but has not been shown to have a positive impact on renal graft function after 3 months.¹⁹ There is some overwhelming evidence that mannitol may be beneficial in treating rhabdomyolysis by stimulating osmotic diuresis. But again, the studies were not randomized and are underpowered.²⁰

NUTRITION

Protein-calorie malnutrition is an independent risk factor for in-hospital mortality for patients with AKI. The nutritional considerations in patients with AKI must take into account a multitude of patient

factors, including metabolic and inflammatory derangements, renal replacement therapy–induced nutrient imbalance, the underlying etiology of AKI, and patient comorbidities.

AKI is associated with hyperglycemia from peripheral insulin resistance, and increased hepatic gluconeogenesis. Hypertriglyceridemia is another consequence of AKI and occurs due to decreased lipolysis and impaired ability to metabolize exogenous lipids.²¹ When considering nutritional supplementation, it should be noted that patients with AKI do not manifest increased energy consumption. The optimal energy to nitrogen ratio is not known. One study of AKI patients on CVVH showed that there was a less negative/weakly positive nitrogen balance with energy intake of 25 kcal/kg/d.²² Another randomized study of AKI patients provided 30 or 40 kcal/kg/d of energy. The higher caloric intake did not improve the nitrogen balance of these patients and instead was associated with worsening hyperglycemia, and hypertriglyceridemia.²³ Therefore, it is reasonable to suggest that patients with AKI be provided with at least 20 kcal/kg/d, but not more than 30 kcal/kg/d.⁴

Protein catabolism is a common finding in critically ill patients, including those with AKI. Consequently, protein intake should not be withheld in order to attenuate the rise in BUN and SCr in order to stave off RRT.⁴ However, administration of high doses of protein have not been proven to improve the nitrogen balance of patients with AKI, and may in fact be associated with increased acidosis, azotemia, and increasing dialysis dose requirements.²⁴ Patients on RRT lose extra protein during therapy in addition to the protein catabolism occurring as a result of their critical illness. Patients on CRRT lose 0.2 g of amino acids per liter of filtrate (5–10 g/d)⁴; patients on intermittent HD may lose less protein per day. The KDIGO guidelines suggest administering 0.8 to 1.0 g/kg/d of protein in AKI patients not on RRT; 1.0 to 1.5 g/kg/d in AKI patients on RRT; and a maximum of 1.7 g/kg/d in patients on CRRT.⁴

Enteral nutrition should be used whenever possible in all critically ill patients, including those with AKI. Critically ill patients may not tolerate enteral nutrition due to delayed gastric emptying and decreased nutritional uptake from bowel

wall edema. The use of enteral nutrition has been shown to improve outcome and survival in ICU patients. The provision of nutrients via the gut helps maintain gut integrity, decreases gut atrophy, and decreases bacterial translocation.

ANTIBIOTIC-RELATED AKI

Aminoglycoside

Aminoglycosides are very potent bactericidal agents that are being used with increasing frequency because of growing antibiotic resistance. The advantages of aminoglycosides include: predictable pharmacokinetics, and lack of hematologic and hepatic toxicity. However, they are also fraught with considerable side effects, including: nephrotoxicity and ototoxicity.⁴ The risk of aminoglycoside induced AKI can be as high as 25%.²⁶ When used appropriately, with proper dosing and monitoring of levels, the risk of AKI with aminoglycosides can be minimized.

Repeated dosing of aminoglycosides results in the accumulation of aminoglycosides in the renal tubular epithelial cells, leading to a higher incidence of nephrotoxicity with repeated exposure.²⁷ Single daily dosing or extended interval dosing can potentially decrease the amount of aminoglycoside that is taken up in the renal tubules and may limit the potential for nephrotoxicity without sacrificing the therapeutic effect.²⁷ Monitoring of aminoglycoside levels during therapy is essential in critically ill patients with frequent fluctuations in GFR.

Amphotericin B

Amphotericin B is a widely used antifungal drug with many systemic side effects including chills, hypotension, cytokine release, thrombophlebitis, electrolyte disturbances, and hypoplastic anemia. Nephrotoxicity is commonly seen with amphotericin B and is the primary dose-limiting side effect.²⁸

Prevention of amphotericin toxicity relies on judicious use of amphotericin. Amphotericin should be avoided, and azole antifungal agents should be used whenever feasible. One major advance in the avoidance of amphotericin nephrotoxicity has been the advent of lipid formulations of amphotericin. The original formulation of amphotericin used deoxycholate as the solvent.²⁸ Clinical trials have

shown that the lipid formulations of amphotericin are less nephrotoxic, while preserving the potent antifungal effect of amphotericin.²⁸

CONTRAST-INDUCED AKI

Many critically ill patients receive diagnostic or therapeutic procedures that require exposure to intravenous (IV) contrast medium. The nephrotoxic potential of contrast media is well known and not inconsequential. Diabetes mellitus, Chronic kidney disease (CKD), and advanced age have been identified as the three risk factors that are common amongst patients that develop contrast induced (CI)-AKI. Preexisting renal disease is the most important risk factor, with the incidence of CI-AKI approaching 25% in this setting.³⁰ Precautions to reduce the risk of CI-AKI should be taken in patients whose baseline creatinine is greater than 1.8 mg/dL.²⁹

Prevention of CI-AKI focuses on the use of non-iodinated contrast media²⁹, minimizing contrast-media volume, avoiding repeat exposure to contrast media, and expanding plasma volume before administration of contrast media. Using iso-osmolar or low-osmolar iodinated contrast media should be used whenever feasible. In general, repeated exposure to contrast should be delayed for 48 hours in patients without risk factors, and for 72 hours in those with diabetes mellitus or previous AKD/AKI. The risk of AKI seems to be highest after inter arterial injection of iodinated contrast media.²⁹ The published literature suggests that periprocedural dialysis has no protective effect against CI-AKI.

Extracellular volume expansion may serve to prevent CI-AKI by a variety of mechanisms. Exposure of the kidneys to radiocontrast agents causes renal damage via a direct nephrotoxic effect, secretion of vasopressin and stimulation of the renin-angiotensin axis (stimulates renal afferent artery vasoconstriction resulting in renal hypoperfusion).²⁹ Extracellular volume expansion causes decreased secretion of vasopressin and also attenuates the renin-angiotensin axis stimulation. Furthermore, by directly diluting the radiocontrast agent, volume expansion may attenuate the direct nephrotoxicity from the contrast. The type of IV fluid used for extracellular volume expansion plays a role in averting CI-AKI. The two solutions that have shown to

help prevent CI-AKI are isotonic normal saline and sodium bicarbonate solutions. The REINFORCE trial, however, found no difference in the incidence of CI-AKI in patients receiving sodium bicarbonate when compared to normal saline.³⁰

There have been many trials examining the use of N-acetyl cysteine (NAC) before contrast exposure in order to decrease the incidence of CI-AKI. Although the evidence supporting the use of NAC in preventing CI-AKI is not particularly strong, considering its negligible side effects, some clinicians include oral NAC along with IV fluid resuscitation as a strategy to prevent CI-AKI.³¹

Renal Replacement Therapy

George Coritsidis, MD and Saad Bhatti, MD

KEY POINTS

- 1 Renal replacement therapy (RRT) is one of the most expensive interventions used in an already cost burdensome intensive care unit (ICU) setting. Prescribing RRT in the critically ill is complex and ideally should involve clear communication between nephrologist and intensivist.
- 2 RRT modalities include peritoneal dialysis, intermittent hemodialysis, continuous renal replacement therapies, and sustained low-efficiency daily dialysis.
- 3 These modalities utilize 2 transport mechanisms in providing renal replacement: diffusion and convection. These forces result in solute **clearance** and plasma water removal or **ultrafiltration (UF)**.
- 4 RRT is initiated early in patients whose renal function is not expected to quickly improve due to severity of illness and is unresponsive to resuscitation: multiorgan failure, high fractional excretion of sodium (FENa), rising azotemia (without plateau of urea or creatinine levels), and oliguria all suggestive of acute tubular necrosis (ATN).
- 5 At present, randomized trials and meta-analyses, do not support a mortality benefit for one modality over another. However, a gradual clearance rate may be wise in hemodynamic instability, acute coronary syndromes, elevated intracranial pressures (ICPs), or hypo/hyponatremia.

INTRODUCTION

Almost 60 years ago, RRT was first used to treat acute kidney injury (AKI) during the Korean War.¹ Within 25 years, continuous therapies were first attempted in Germany.² RRT modalities have since expanded, becoming commonplace in most hospitals of the developed world. In AKI, when preventative and supportive management fails we turn to RRT.

In the past decade, admissions for AKI increased with a doubling in the incidence of severe AKI (Figure 31–1).³ In parallel, approximately 200,000 patients required RRT in 2012.³ The incidence of RRT-requiring AKI now surpasses that of end-stage renal disease (ESRD).⁴ What's more, the morbidity

and mortality of AKI requiring RRT extends beyond hospitalization.^{3,5}

The necessity for RRT in the ICU arises in 1 of 3 clinical situations: AKI, critically ill ESRD patients,⁶ and drug or toxic overdoses. RRT for AKI is dramatic but less common than most think. The incidence of AKI in the ICU is relatively low between 6% and 19%, but can be higher depending on population studied and risk, injury, failure loss, and end-stage kidney disease (RIFLE) criteria.^{7,8} RRT needs occur in up to 5% of AKI.^{8,9} Unfortunately, mortality continues to remain high, between 24% and 50%.^{3,8,10} AKI incrementally adds to short- and long-term mortality, and especially when RRT is

FIGURE 31–1 Population incidence of dialysis-requiring acute kidney injury (AKI) in the United States from 2000 to 2009 (count and incidence rate per million person-years). I bars represent 95% confidence intervals (CIs). The number of cases of dialysis-requiring AKI increased from 63,000 (2000) to almost 164,000 (2009); population incidence increased 10% per year from 222 to 533 cases/million person-years.³ (Reproduced with permission from Hsu RK, McCulloch CE, Dudley RA, et al: Temporal Changes in Incidence of Dialysis-Requiring AKI, *J Am Soc Nephrol* 2013 Jan; 24(1):37-42.)

required,^{6,9} with up to 14% requiring chronic dialysis on discharge.^{5,8,11}

Prescribing RRT in the critically ill is complex and ideally should involve clear communication between nephrologist and intensivist.¹² The choice of modality, the goals, its timing, as well as patient-specific findings, are collectively crucial in the decision for RRT.¹² Understanding the shortcomings and function of the modalities must also be a part of the process. In centers where selection is limited to intermittent hemodialysis (IHD), adaptations are not only viable but presently adequate.¹³

RRT: PHYSIOLOGY

Clearance of any substance depends on modality characteristics, (convection vs diffusion), size, time on RRT, flow rates (both blood and dialysate), and dialyzer membrane characteristics (Figure 31–2).¹⁴ This is coupled with patient acuity, hemodynamics, nutritional status, volume status, and diagnosis determines eventual success.

RRT attempts to support the kidneys' responsibilities in maintaining homeostasis. To some extent it

succeeds in volume control and to a lesser extent in solute and acid/base homeostasis. The various modalities, whether peritoneal or hemodialysis, utilize 2 transport mechanisms in providing renal replacement: diffusion and convection. These forces result in solute **clearance** and plasma water removal or **UF**. Other renal responsibilities such as calcium/phosphate balance and anemia control are not provided with RRT.

Clearance, removal of solute from plasma, is most efficiently accomplished by diffusion. Namely plasma is cleared of certain solutes across a semipermeable membrane (the dialyzer), as it travels down a concentration gradient. Each fluid medium (plasma and dialysate), flows in a direction counter current to the other, maintaining the concentration gradient between plasma and dialysate. Hence a plasma potassium of 7 mEq/L approaches that of the dialysate's 2 mEq/L over time. Dialysate can be adjusted to approximate the desired goal of net solute change. Clearance is determined by the solutes' serum concentration, molecular weight, and dialysis membrane characteristics (pore size and surface area). Diffusion becomes relatively inefficient as solute molecular weight increases, while with convection

FIGURE 31–2 Mechanisms of solute clearance in various modalities of Renal Replacement. TMP, transmembrane pressure, or hydrostatic pressure; UF, ultrafiltration; •, * = solutes.

large-molecular-weight solute clearance is more effective.¹⁵ Diffusion is a key mechanism of clearance in RRT using dialysate such as IHD.

Convection, which is preferred in treating the critically ill, is capable of removing large quantities of “plasma” water or UF. Blood hydrostatic pressure in the dialyzer supports a transmembrane pressure, through which UF is generated. Accompanying UF is the clearance of solute via **solvent drag**, signifying that this fluid is not pure water but

laden with solute. In fact, convection plays a significant role in providing clearance in continuous RRTs. UF rate is what determines clearance and is dependent on blood flow rate. Though inefficient in providing clearance, convection by adding the luxury of 24 hours surpasses what IHD can do in 4 (Figure 31–3).

An added benefit with convection is the enhanced clearance of larger molecules or middle molecules (500–5000 Da), felt to include uremic toxins. There are over 115 compounds identified as toxins that correlate more closely with uremic symptoms such as encephalopathy.¹⁶ Since middle molecule clearance depends on the duration of a plasma-dialysate interface, continuous RRTs are more effective. Though at present conjectural, middle molecule clearance may in time provide for an important element of treatment in AKI due to sepsis. For instance, evidence indicates that continuous modalities may enhance clearance of various mediators of inflammation (see later).

RRT: INDICATIONS

RRT indications include the critically ill ESRD patient, the critically ill AKI patient, and the toxic overloaded patient. Only the first 2 are actual renal replacement.

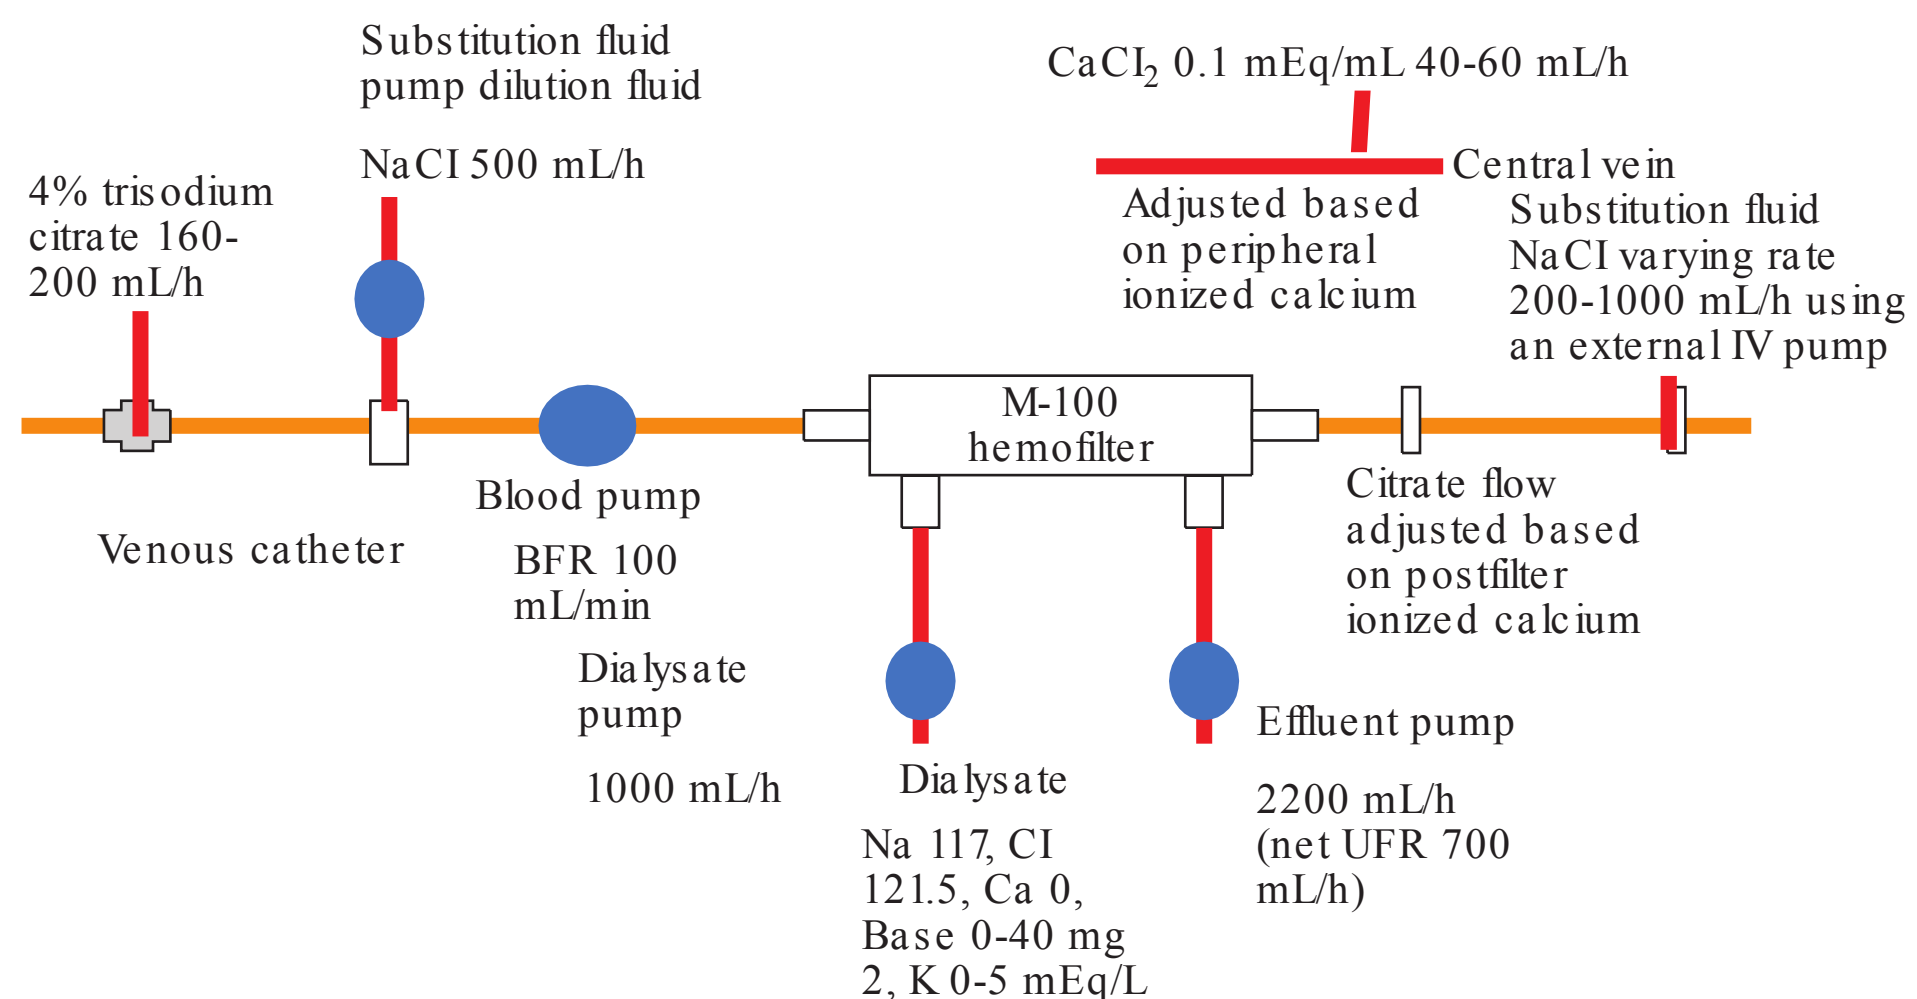

FIGURE 31–3 Continuous renal replacement therapy (CRRT) circuit (Gambro PRISMA and M-100 filter). Regional citrate is infused for anticoagulation; CaCl_2 adjusts peripheral ionized Ca levels; substitution fluid (replacement fluid [RF]) can be either pre- or postfilter and determines net fluid balance; effluent represents spent dialysate and/or UF. (Reproduced with permission from Mehta RL, et al. Continuous renal replacement therapy in the critically ill patient, *Kidney Int* 2005 Feb; 67(2):781-795.)

The Critically Ill ESRD Patient: Maintenance Dialysis

RRT for ESRD patients may be the most common reason (up to 40% of all patients receiving RRT) for its use in the ICU.^{6,17} The etiology is most often related to ESRD comorbidities, primarily cardiovascular problems (31% of ICU ESRD cases) and most commonly arrhythmias and congestive heart failure.⁶ Admissions may result from missed dialysis and/or compliance issues resulting in volume or electrolyte imbalances. ICU monitoring provides ventilator support, or if hyperkalemic, telemetry for possible arrhythmias, or cardiogenic shock. After prompt RRT the patient is stabilized, often resulting in relatively short admissions.

ICU care may also be required for acute events unrelated to ESRD, such as sepsis (15% of ICU ESRD cases), trauma, or complications from surgery. They have twice the rate of sepsis and higher readmission rates than nonrenal failure patients.^{6,17} Mortality is lower than AKI patients requiring RRT, but higher than the general population.

The Critically Ill AKI Patient: Bridge RRT

In treating AKI, RRT is supportive, bridging the patient while treating the initiating event. About 7.5% of hospitalized patients with AKI require RRT.⁵ In the ICU, AKI is most often due to sepsis thought to be from ATN, though glomerular hemodynamics play a significant role.^{8,18} The need for RRT is relatively uncommon in AKI when all RIFLE classes are included. It requires a process of involved decision making between nephrologist and intensivist: recognizing the patient's needs; weighing issues of hypotension and anticoagulation; selecting the proper RRT; and balancing them with realistic capabilities. This includes possibly avoiding RRT, waiting for renal recovery, or not even considering it due to futility.

Emergent RRT

Clear indications for immediate RRT include life-threatening hyperkalemia, severe metabolic acidosis, and volume overload; overt symptomatic manifestations of uremia such as pericarditis and encephalopathy; and intoxications (lithium, aspirin, ethylene glycol, methanol, metformin, amanita).

Adequate treatment of uremia through the clearance of uremic toxins is unclear since such toxins are not clinically measured.¹⁶ Since, for every small increment of creatinine there is a significant rise in mortality,¹⁹ uremic toxins may be clinically more important than realized. Unfortunately, we are limited to assuming uremia in the azotemic patient with a pericardial rub, or encephalopathy. Given the multiple reasons for mental status changes in the ICU, the encephalopathy is particularly difficult to discern and ideally RRT should be initiated well before uremic symptoms occur.

In uremic pericarditis, treatment is daily, continued RRT. When entertaining the diagnosis, it is important to evaluate and rule out, cardiac tamponade. Aggressive RRT without initial decompression may decrease preload and result in shock.

Early or Urgent RRT

RRT is initiated early in patients whose renal function is not expected to quickly improve due to severity of illness: multiorgan failure, AKI unresponsive to resuscitation, high FENa, rising azotemia (without plateau of creatinine or urea levels), and oliguria all suggestive of ATN. In such "extreme" conditions the concept of early RRT to replace renal function and/or support multiorgan dysfunction may make most sense and benefit.²⁰ RRT maintains volume despite hemodynamic, nutritional, antibiotic, and other infusion needs, while providing balance of electrolytes and pH.

The decision for early RRT remains a difficult one especially since the benefits to mortality or otherwise is not clear.²¹ A meta-analysis of 30 RCTs and 8 prospective cohort studies was inconclusive,⁹ while a recent meta-analysis of 23 studies (1960-2006), suggested some benefit.²² Importantly, these trials differed considerably in clinical settings and definitions of early RRT. Many excluded patients that recovered or died without starting RRT, rendering a recommendation for early RRT difficult.

The question becomes more complicated prompting clinical discussion in less dramatic presentations, such as nonoliguric AKI,²³ and/or slow rising azotemia (risk or injury on the RIFLE scale). Since there is no key single marker to use as a starting point for RRT, the decision is based on the multiple facets of the presentation.

Traditional markers of AKI, serum creatinine and blood urea nitrogen (BUN) are limited in this regard, though, a lower mortality risk has been reported when starting RRT at lower BUN levels.^{26,27} Urea generation (BUN levels) varies depending upon protein intake and catabolism²⁶. Its highly variable volume of distribution (Vd) is exemplified by the BUN rebound seen in sepsis after RRT. What's more, dialysis efficacy using urea kinetics has not been assessed in either AKI or in the critically ill.¹⁴

Pursuing this question, the BEST study²⁸ separated azotemic patients by BUN, creatinine, and time in ICU. The answers were mixed. In the BUN-based analysis, there was no outcome difference in timing of RRT.²⁸ "Late" initiation based on creatinine had lower mortality while those initiated early based on ICU duration prior to RRT had lower mortality. These observations were confounded due to some having chronic kidney disease (CKD) and variability in patient presentations. However, the study did suggest that early RRT in patients with preexisting CKD may impart a higher survival advantage.²⁸

Another reported reason in delaying RRT is the perception of impending renal recovery.²⁵ RRT is invasive and can result in complications from access placement, hypotension, electrolyte abnormalities, and arrhythmias.^{13,29} Hemodynamic instability is common in the ICU and the intensivist needs to balance RRT safety with its need. Hypotension during RRT, along with issues of dialyzer bioincompatibility may delay renal recovery.³⁰ Dialyzer membranes induce monocyte-derived proinflammatory cytokines (interleukin [IL] 1, 6, 8, tumor necrosis factor alpha [TNF- α]), which can increase renal toxicity. So-called biocompatible membranes may lessen these responses. Therefore when taken into account a prudent decision may be to wait and monitor volume, potassium, protein intake, and supplement bicarbonate as needed, selecting extended or continuous RRTs if condition worsens. Recently published AKIKI trial with early vs late initiations of RRT in critically ill patients suggest delaying initiation based on clinical indications may avoid the need for RRT. ELAIN trial suggests reduced 90 days mortality with early RRT initiation.^{25,26}

Finally, delays can also arise from issues of logistic support involving nursing and staff availability as well as their timeliness.²⁵

Fluid Overload

In severe sepsis and AKI, positive fluid balance is independently associated with increased mortality.^{31,32} Recent studies suggest fluid overload to be more critical indication for initiating RRT earlier. In both the pediatric and adult literature, fluid overloaded patients had better outcomes with early RRT even after severity of illness adjustments.^{31,33} Furthermore, survivors had lower fluid accumulation at RRT initiation compared to nonsurvivors even with RRT modality and severity adjustments. Always influential, volume status may now provide a greater urgency for early RRT.

Fluid overload is also associated with more days on dialysis, and greater ICU and hospital length of stay.^{28,34} Though adjusted for severity, it is not clear the difference in volumes suggest hemodynamically dissimilar patients or that volume should be applied more conservatively and/or ultrafiltrated more aggressively.

Cessation

Similar to commencement, no prespecified single finding or estimated glomerular filtration rate (eGFR) exists to trigger cessation. Actually, attempting to assess GFR is inaccurate when renal function is not in steady state. As patient acuity improves, the first decision is to transfer to IHD. In deciding, it is important to consider if IHD can support present and daily volume load. Moreover, drug dosing must be adjusted to IHD or level of renal function.

In general, RRT is terminated when urine output increases and creatinine is stable or decreases. The return of renal function is often preceded by an improvement in the patient's overall condition. Continuing may not only be unnecessary but any RRT, and possibly more so IHD, may delay renal recovery from hypotension and/or continued inflammation. Conversely, continued RRT may be of benefit for maximizing uremic toxin clearance.³⁵ The answer is not known.

RRT: MODALITIES

The coupling of adequate solute and UF control with satisfactory patient outcomes are the goals of RRT. Practical issues that include nursing scheduling and

TABLE 31–1 Comparison of the RRT modalities.

Modality	1 ^o Mode of Clearance	BFRcc/min	Dialysate	RF	Anticoagulation	Time
IHD	Dif usion	250-400	Yes	No	Short heparin	3-4 h
SLEDD	Dif usion	100-200	Yes	No	Long heparin	8-24 h
CVVH	Convection	200-300	No	Yes	Continuous heparin/citrate	24 h
CVVHD	Both	200-300	Yes	Yes	Continuous Heparin/citrate	24 h
SCUF	Convection	100-200	No	No	Long heparin/citrate	Variable

BFR, blood flow rate; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodiafiltration; IHD, intermittent hemodialysis; RF, replacement fluid; SCUF, sustained continuous ultrafiltration; SLEDD, sustained low-efficiency daily dialysis. Data from Schortgen F, Soubrier N, Delclaux C, et al: Hemodynamic tolerance of intermittent hemodialysis in critically ill patients: usefulness of practice guidelines, *Am J Respir Crit Care Med* 2000 Jul;162(1):197-202.

cost are coupled to the patient’s presentation when selecting the RRT modality (Table 31–1).

Peritoneal dialysis

In North America, peritoneal dialysis (PD) was extensively used into the 1990s to treat AKI in the ICU.³⁶ PD requires placement of an intra-abdominal catheter, with continuous exchanges of high dextrose dialysate into the abdominal cavity. PD, therefore, is a continuous RRT. The high osmolarity dextrose generates UF, and hemodynamically it tends to fare better than IHD. Catheters were temporarily placed at the bedside by nephrologists, or Tenckhoff catheters were placed by surgeons. In the following decades, acute PD was largely abandoned due to inefficient solute clearance, infection concerns, and its contraindication in patients with abdominal problems or recent surgery. PD may also be difficult in ventilated patients or in severe obstructive lung disease.

Recently, the modality has been reassessed in the ICU setting, where the use of high-volume PD was examined.³⁷ One study which excluded severely hypercatabolic patients, had few complications (7.5%) and 12% had peritonitis. In certain critically ill patients, PD may be a viable alternative,³⁷ where its characteristic continuous slow clearance may better suit patients with elevated ICP.³⁸

Intermittent Hemodialysis

It is essentially conventional outpatient dialysis averaging 4 hours, 3 times per week, with blood flow rates (BFR) up to 400 cc/min. Due to the higher BFR

and dialysate flow rates (DFRs) it is more likely to induce hypotension than other modalities. Therefore, the traditional arguments against using IHD in the ICU have been relatively less hemodynamic stability and clearance compared to continuous RRT. Furthermore, IHD is also a concern in situations where rapid changes in solute (sodium or potassium) or osmoles (elevated ICP) can be detrimental (see below). Financially, the use of roller blood pumps and rapid clearance requires skilled dialysis nursing, increasing costs.

Earlier studies demonstrated IHD a hemodynamic risk compared to continuous RRT (CRRT). Since then, advancements such as in-line bicarbonate baths and biocompatible membranes have improved IHD stability.^{30,39} Presently, IHD is the most commonly selected RRT in American ICUs, utilized in 57% of cases.⁴⁰

Furthermore, in the severely ill, nephrologists can improvise IHD by slowing BFR, increasing hours and/or increasing its use to 6 d/wk. This increases net clearance while maintaining hemodynamic stability, essentially becoming sustained low-efficiency daily dialysis (SLEDD) (see later). What’s more, adding a separate UF procedure (blood through the dialyzer without counter current dialysate, excising diffusion), facilitates volume removal with less hypotension. UF is better tolerated when solute and osmole clearance is not concomitant.

In the critically ill requiring the use of vasopressor agents, IHD may still be attempted by increasing the dose of the vasopressor as needed. The suggested guidelines in Table 31–2 can largely be met by most institutions.

TABLE 31–2 Guidelines for IHD in critically ill patients.^a

- Biocompatible, modified cellulosic membranes (not cuprophane)
- Connect both sides of circuit simultaneously with .9% saline at start
- Adjust dialysate sodium at 145, calcium 1.5 mmol/L
- Limit maximum blood flow to 150 mL/min
- Increase time on dialysis and/or days per week (6 days per week)
- Dialysate temperature $\leq 37^{\circ}\text{C}$
- Stop vasodilators; increase vasopressors as needed
- Start with dialysis and then continue with ultrafiltration alone
- Ultrapure water

^aAdapted from Schortgen F, Soubrier N, Delclaux C, et al. Hemodynamic tolerance of intermittent hemodialysis in critically ill patients: usefulness of practice guidelines. *Am J Respir Crit Care Med.* 2000;162:197-202.

Continuous Renal Replacement Therapy

Continuous modalities (see Table 31–1) are considered in hemodynamically unstable patients less likely to tolerate abrupt fluid shifts associated with IHD. CRRT is distinguished by lower BFR, allowing for greater stability in treating fluid overload. Indeed, fluid accumulation is more likely seen with IHD than CRRT.³³ Also, acidosis and volume control are more consistent with CRRT. Both convective and diffusion modes of solute clearance can be utilized depending on CRRT type. Surprisingly, outcome benefits of CRRT over IHD have not been demonstrated.

Patients for which CRRT is preferred include those with hypotension as in severe sepsis, cirrhosis, liver transplant, and congestive heart failure (CHF). It also benefits patients with markedly elevated BUN and/or ICP due to gradual solute removal avoiding disequilibrium.

As implied, CRRT is administered continuously for as long as required. In actuality, due to interruptions for diagnostic and/or therapeutic interventions treatment time is closer to 18 hours. The long duration on the CRRT circuit cools the blood, resulting in reflexive vasoconstriction supporting hemodynamics.⁴¹ CRRT can be used in operating rooms during prolonged procedures such as liver transplantation, and requires frequent hemodynamic, laboratory and electrolyte assessments.

Continuous Arteriovenous Hemofiltration

Arteriovenous modalities (continuous arteriovenous hemofiltration [CAVH] and continuous arteriovenous hemodialysis [CAVHD]) required placement of catheters in an artery and central vein. This system utilized the patient's arterial pressure rather than a rolling pump for blood flow. CAVH is rarely used since the advent of continuous venovenous hemofiltration (CVVH) due to more invasive arterial access, variable BFR, and increased filter clotting issues.

CVVH

Essentially through convection, clearance is dependent on large UF rates. To maintain hemodynamic and electrolyte stability large volumes (between 1 and 3 L/h) of electrolyte solutions are necessary. Frequent close attention to volume and electrolyte status is essential. Effluent flow is reported as mL/kg/h. The difference between infused volume and UF generated is the net fluid balance. Recent studies have not demonstrated superiority of a particular flow over another.²⁹

REPLACEMENT FLUIDS:—Replacement fluids (RFs) are provided as prefilled sterilized bags by the equipment manufacturer. They have varying concentrations of sodium, magnesium, calcium, and potassium, and allow for modification. Either bicarbonate or lactate is the alkali source. Ideally, lactate-based RF should be avoided in liver failure and/or lactic acidosis, and periodic lactate measurements are needed with bicarbonate replacement when higher than 5 mmol/L.⁴² Bicarbonate has become the buffer of choice despite issues with storage and preparation.

The RF with the added clearance of solute has effects on blood composition and requires periodic monitoring of blood chemistries. It is added either before the dialyzer (predilution/inflow) or after blood has passed through the dialyzer (postdilution/outflow).

Predilution RF lowers (dilutes) solute concentration and theoretically decreases CVVH clearance efficiency. The UF is not 100% saturated with urea having been diluted by RF prior to passage through the dialyzer/filter. Advantages lie in requirements of

low BFR and less clotting of circuit also due to the dilutional effect of the RF.

In postdilution outflow mode, UF rate should not be more than 20% of BFR to avoid excess hemoconcentration and clotting of the circuit. T is requires higher BFR of 150 to 200 mL/min to achieve adequate fluid removal in excess of 25 L/d. Predilution inflow overcomes this problem at the expense of clearance efficiency but overall better treatment due to less clotting and more fluid processed for UF generation.⁴³ As an example, 35 L of daily replacement fluid addition in predilution/inflow mode dilutes the blood by 15% at a BFR of 140 mL/min. ($35 \text{ L/d} = 24 \text{ mL/min}$; $24/140 + 24 = 15\%$).

Continuous Venovenous Hemodiafiltration

Diffusion is now introduced enhancing clearance, by running dialysate countercurrent to blood flow in the extracorporeal circuit. As a combined modality, it requires large volumes of RF in maintaining hemodynamic and electrolyte stability. Again, close attention to the volume and electrolyte status is essential. Comparing CVVH to continuous venovenous hemodiafiltration (CVVHDF) meta-analysis has failed to show any benefit in mortality, renal recovery, vasopressor use, or organ failure.⁴⁴

Anticoagulation

All RRT requires anticoagulation to avoid circuit clotting that can result in blood loss, fluid administration to flush the circuit, and minimize blood loss. Treatment disruption to replace the circuit, associated costs for dialyzer and line changes, and resource utilization of personnel, since many institutions mandate dialysis staff to replace circuits. Due to lower BFRs, CRRT have higher clotting risks than IHD.

As in IHD, heparin is the preferred anticoagulant. It is intravenous (IV) bolus administered in the venous line, 2000 to 5000 units, allowing a few minutes to mix. Maintenance is 500 to 1000 units/h infused by roller pump into the arterial line. Partial thromboplastin time (PTT) is measured via arterial and venous lines every 6 hours to maintain PTT 40 to 45 or greater than 65, respectively.

In patients with heparin-induced thrombocytopenia direct thrombin inhibitors are used.⁴⁵ Argatroban is preferred in renal patients at 0.5 to 1 µg/kg/min,

due to its liver metabolism.⁴⁶ Lepirudin is renal eliminated and may be administered as bolus or infusion (0.005-0.025 mg/kg/h). A target activated partial thromboplastin time (aPTT) greater than 1.5 to 2 times normal avoids excessive bleeding and ensures anticoagulation. Fresh frozen plasma is employed for reversal of bleeding attributed to these direct thrombin inhibitors.

Anticoagulation should be reviewed daily between intensivist and nephrologist, and if contraindicated, heparin-free treatments are possible. In SLEDD periodic, every 15 to 30 minutes, saline flushes are instituted. In CVVH, RF is infused pre-filter to avoid hemoconcentration.⁴⁷ Heparin-free extracorporeal circuits on average clot over 8 hours. Decrease in dialysate/serum BUN levels to less than 0.6 may indicate imminent clotting.

Regional citrate avoids systemic anticoagulation, and is superior in circuit survival and bleeding complications.⁹ Citrate can be administered either before or after blood has been exposed to the filter. Commercially available solutions include ACD-A which has 3% trisodium citrate, citric acid, and dextrose. Using calcium-free RF decreases the amount of citrate required for anticoagulation. Periodic assessment of bicarbonate levels and ionized Calcium (iCA), both from the extracorporeal circuit and patient, is mandatory to avoid serious hypocalcemia. The citrate administration or calcium supplementation is titrated to keep the postfilter iCA between 1.21 and 1.45 mmol/L. Infusion of calcium into circuit avoids delivery of hypocalcemic blood to patient. Citrate toxicity can be a concern in patients with liver disease or lactic acidosis.⁴⁸

Staffing CRRT requires intense attention to patient care, necessitating one-to-one nurse-to-patient ratios. Elevating the head of the bed or turning the patient can compromise flow and risk clotting, making positioning an issue. In the case of femoral access, better flow is obtained in the supine position.⁴⁷ Also, some institutions require hemodialysis staff to assist at CRRT commencement, interruption, or termination.

Equipment CVVH equipment is smaller in size since water purification filters in RRT requiring dialysate (IHD, CVVHDF, or SLEDD) are not necessary. The basic operating principle is similar to IHD as a blood pump is utilized to circulate

blood through the dialyzer/filter to generate UF (see Figure 31–3). CVVH machines are now equipped with temperature regulation mechanisms resulting in added hemodynamic effects of vasoconstriction at lower temperatures. The febrile response to infection can therefore be missed. Despite impressive advancements in practicality and compactness of machines, it is still necessary to interrupt CRRT for transportation.

Access Any preexisting ESRD access can be utilized for CRRT. In AKI requires placement of a double-lumen catheter in either the femoral or internal jugular (IJ) vein regardless of RRT. These catheters have staggered openings allowing blood flow out from the patient via the proximal (insertion site) opening and return via the distal opening. This arrangement diminishes the degree of mixing or recirculation, and hence, inefficiency.

In general, site selection for catheter placement follows similar risks such as bleeding and infection. Subclavian and left IJ veins are avoided when possible due to the angulation necessary for proper placement and flow. The stiffer catheter risks vessel injury, compromising blood flow and clotting. Furthermore, the subclavian catheter can cause stenosis resulting in high venous pressures, making the creation of a permanent AV access difficult. Up to 14% of AKI patients may need permanent chronic dialysis.^{5,8}

Sustained Low-Efficiency Daily Dialysis

Also called extended dialysis (ED), it is a hybrid of CRRT and IHD. It is increasingly utilized throughout the world,⁴⁹ as well as in the United States, where about 25% of ICU providers reported using SLEDD in 2007.⁴⁰

SLEDD generally runs daily for 8 to 10 hours with low DFR (200–400 cc/min) and BFR (150–200 cc/min). It can utilize the IHD machinery with added software to support a lower BFR allowing for a more gradual solute and/or fluid removal. Time on SLEDD can be extended up to 24 hours, to provide for greater clearance according to perceived needs by providers.⁵⁰ The filters have smaller surface areas (1 m² compared with 1.5 m² for IHD), lower UF coefficients (10 mL/h/mm of Hg compared with 45), and lower K₀As (maximal theoretical clearance of dialyzer of 600 mL/min compared with 1000 mL/min), but are similarly composed of polysulfone.

SLEDD's hybrid properties support hemodynamics, enhance clearance, and increase convenience while lowering costs. This, as well as its versatility, accounts for a rising popularity.⁴⁹ For instance, it often is utilized overnight (nocturnal dialysis) when the probability for interruption from procedures or radiologic examinations is less likely. Such maneuvers better guarantee the prescribed dialysis without interruption. Still another important benefit is the decreased need for heparin, not being continuous.

Most importantly, these benefits come without compromising outcomes in AKI as compared to CRRT.⁴⁹ In a recent study,⁵⁰ the net 24-hour UF and fluid balances were similar between CVVH and SLEDD, as were hypotensive episodes. Furthermore, SLEDD was associated with a fewer days on mechanical ventilation and in the ICU.

Sustained Continuous UF and Fluid Removal in Severe CHF

Though technically not RRT, extracorporeal modalities for UF are considered in severe CHF with diuretic resistance. In such patients renal impairment is not the overwhelming reason to initiate sustained continuous UF (SCUF) but rather as an alternative to diuretics. To date various studies, the UNLOAD and others, have not demonstrated any renal or length-of-stay advantages.⁵¹ SCUF should probably be relegated to patients who failed medical therapy and are awaiting cardiac transplant (see Table 31–1).⁵²

Dosing

Unfortunately, significant questions involving RRT, namely the exact clearance provided, how much is necessary and when to provide it are poorly understood. Dosing should indicate a measured effectiveness of the ridding of waste products from a given volume of blood.¹⁴ Urea kinetic modeling, which is ESRD based, is questionable in assessing efficacy in the critically ill, given their increased catabolism and urea V_d.^{14,26}

Treatment dosing (volume of fluid processed) utilizes urea generation (g) over 24 hours (the difference in BUN levels 24 hours apart + loss in urine in nonoliguric AKI) as a marker, divided by the target

BUN (g/L). For a 60-kg individual, water compartment is 33 L (0.55% of body weight). Total body urea = BUN level in g/L X's body water (add edema volume to this). The difference between 2 values 24 hours apart + urine loss of urea is total urea generation (g) in 24 hours. If urea production is 16 g/d and target BUN is 40 mg/dL (0.4 g/L), 16/0.4, 40 L of fluid needs to be processed to achieve the clearance and maintain BUN at 40 mg/dL. This however is not generally done when utilizing these modalities. In fact most providers are uncertain of prescribed dosing.⁵³

Past RRT trials have not used urea clearance as a study goal. Guidelines suggest a CRRT KT/V of 3.9/wk or an effluent volume of 20 to 25 mL/Kg/h.⁵⁴ To achieve this a higher prescription of 25 to 30 mL/kg/h may be necessary. What's more, CVVHDF studies suggest using doses at 35 mL/kg/h.

Antibiotic Management The most common cause of AKI in the ICU remains sepsis⁸ and despite advances, the mortality has not appreciably improved.^{3,6,13,29} Though the reasons are likely multifactorial, recent attention on antibiotic (AB) dosing during RRT has identified an important shortcoming (Table 31–3).⁵⁵ High-flux membranes with larger surface areas and increased time on RRT (CRRT or SLEDD) remove ABs more efficiently compared to IHD. In these forms of RRT, eGFR provided may be up to 30 mL/min and as many as 25% of patients are not making pharmacokinetic targets.⁵⁵ Furthermore, difficulties in dosing are further compounded when considering modality variability and intermittent usage.⁵⁶ Given data supporting improved mortality with adequate AB dosing, this is a legitimate concern for septic patients on RRT.

SELECTION OF RRT: SPECIAL CONSIDERATIONS

Avoiding Rapid Changes in Osmolarity and Electrolyte Levels

In patients with hemodynamic uncertainty it may be prudent to select a modality other than IHD. However, there are at least 3 scenarios where a gradual clearance rate may be wise even with hemodynamic stability: in the setting of acute coronary syndromes, elevated ICPs or hypo/hyponatremia. In such cases the issue is avoiding an abrupt solute or osmole change rather than hemodynamics.

Rapid decline of potassium levels in ESRD patients with acute myocardial infarction (MI) may increase the risk for arrhythmias.⁵⁷ Longer RRT time with lower BFR achieves a gradual safer decrease in potassium levels. Continuous RRT is ideal for such a presentation.

In patients with raised ICP or its potential, standard IHD should be avoided. Abrupt decreases in urea with resultant fluid shifts in the central nervous system (CNS) can result in worsening cerebral edema. Similarly, gradual decreases in urea concentration using continuous, sustained, or peritoneal dialysis are better tolerated.³⁸ These modalities also provide some insurance against hypotensive episodes, which by lowering cerebral perfusion pressure adds to the injury. Here too, if other modalities are not available, IHD slowed down to BFR of 150 to 200 cc/h as discussed earlier should be sufficient.

Finally, rapid normalization of sodium levels in patients with hyper- or hyponatremia can induce central pontine myelinolysis and/or edema.

TABLE 31–3 Suggestions to consider when antibiotics (ABs) are to be used.^a

1. ABs are either time dependent (TD) or concentration dependent (CD) and should be approached and adjusted accordingly.
2. For TD ABs (beta-lactams, linezolid, vancomycin, erythromycin) increase the frequency of the dose to maintain levels. In TD ABs, it is the time spent above the MIC that is crucial.
3. For CD ABs (fluoroquinolones, aminoglycosides, metronidazole, daptomycin, colistin) increasing the dose maintains levels. In CD ABs it is desirable to have high peaks and low troughs to enhance bactericidal activity while diminishing toxicity.
4. The Vd in AKI is altered, often higher than normal. It may be preferable to give the first 1 or 2 doses as if the patient's renal function is normal, then adjust to function. In CRRT assume creatinine clearances of 30 cc/min.
5. Use therapeutic monitoring where possible.
6. Other systems such as ECMO and nonoliguric patients may increase AB clearances.

^aData from Eyler RF, Mueller BA: Antibiotic dosing in critically ill patients with acute kidney injury, *Nat Rev Nephrol* 2011;7:226–235; Connor, Jr. M, Salem C, Bauer, S, et al: Therapeutic Drug Monitoring of Piperacillin-Tazobactam using Spent Dialysate Effluent in Patients Receiving Continuous Venovenous Hemodialysis, *Antimicrob Agents Chemother* 2011;55:557-560.

Likewise, dialysis disequilibrium syndrome is due to rapid reduction of high urea levels. Use of gradual RRT, close monitoring, and intravascular fluids can help guarantee safe normalization.

Endotoxin Removal

There are multiple systems studying endotoxin removal in sepsis such as high-volume hemofiltration and hemoperfusion with polymyxin B embedded polystyrene absorbing surfaces. One issue of controversy is that anti-inflammatory cytokines and factors are removed as well.⁵⁸ Small studies have shown decreases in cytokines with inconsistent outcome effects.⁵⁹

RRT OUTCOMES: MORTALITY, RENAL RECOVERY, AND COST

Renal Recovery

In general, AKI patients requiring RRT recover significant renal function, not requiring chronic dialysis. However, up to 14%, primarily those with baseline CKD, will continue RRT.^{5,8} Recently, Wald et al⁶⁰ demonstrated that dialysis-requiring AKI was associated with an increased risk for later ESRD (adjusted heart rate [HR] 3.2; 95% confidence interval [CI] 2.7-3.9) compared with controls matched for age, gender, CKD status, need for mechanical ventilation, and a propensity score for dialysis-requiring AKI.

As to the benefits of one RRT modality versus another in supporting renal recovery, CRRT may be preferred. The suggestion is that better hemodynamic control, solute clearance, and maintenance of acid-base, may be more natural with CRRT. Though not seen in all studies, a recent review of 16 observational and 7 randomized controlled trials (RCTs) suggests CRRT benefits renal recovery (relative risk IHD vs CRRT of 1.73, $P = 0.02$).⁶¹ Significance was not seen when limiting the study to RCTs, and does not distinguish SLEDD from IHD. If this leads to less ESRD, then the use of CRRT may benefit quality of life as well as long-term costs.⁶²

Cost

RRT is one of the most expensive interventions used in an already cost burdensome ICU setting.⁶²

Cost is primarily personnel, whose need is largely related to the selected modality's degree of complexity. Furthermore, RRT patients inevitably have longer lengths of stay.⁵ CRRT modalities being the most complicated and requiring the most supplies (replacement fluid, tubing, etc) are the most expensive, by as much as thousands of dollars per week.⁹ Of the RRTs, a number of studies have indicated SLEDD to be the least expensive, largely due to decreased nursing needs.⁵⁰

Mortality and Outcomes

ICU patients with AKI requiring RRT have a higher mortality than other ICU patients including those with ESRD or AKI without need for RRT.^{6,8} Despite over 35 years of experience and improvements,^{2,30,39} there still remains an unfortunate mortality of between 25% and 50%.^{3,6,10,13,29}

The long-standing controversy is whether CRRT is superior to IHD in regards to mortality. At present the predominant evidence, randomized trials, and meta-analyses, do not support a mortality benefit for CRRT.⁹ Still the recent KDIGO AKI guidelines prefer CRRT (level 2 recommendation), over IHD, for hemodynamically unstable patients.⁵⁴ What's more, there does not seem to be a mortality advantage with larger delivered clearance doses.^{9,13,29} Palevsky reviewed 2 cohorts of AKI patients receiving RRT, one attaining a higher intensity and therefore higher RRT dose compared to a second lower dose; no mortality advantage was demonstrated.¹³ Similarly, higher CVVH doses have not demonstrated any mortality benefits (Table 31-4).²⁹

Shortcomings: What Explains These Shortcomings is Likely Multifactorial

First the modalities themselves: Closer monitoring is vital. In the Palevsky study, which demonstrated a lack of benefit with intense RRT, it is notable that there was a greater need for vasopressor support in this group despite the use of continuous RRT.¹³ Moreover, there was significantly more hypokalemia and hypophosphatemia. The latter also seen in the higher UF group of the RENAAL study.²⁹ In the critically ill, electrolyte abnormalities and/or their rapidity⁵⁷ may result in morbidity and even mortality (Table 31-5).

TABLE 3 1–4 General summary of various aspects of RRT management and potential risks.

1. Early, nonemergent, RRT should be considered in azotemic, oliguric patients with AKI and a high acuity level not likely to timely improve. a. Increased consideration made for evidence of CKD and volume overload. b. Consider continuous or slowed modalities in severe electrolyte disturbances, azotemia, and in patients with possible elevated ICP.
2. Inadvertent removal and underdosing of antibiotics or other therapeutic agents. a. Adjust antibiotics. b. Other catheter systems such as ECMO may also increase clearances.
3. Depletion of trace nutrients, adjustment in protein dosing. a. Protein restriction should not be used to prevent the need for RRT. b. Once RRT begins daily protein intake should return to the suggested needs in critically ill patients without AKI (1.5 g/kg/d; up to 1.7 g/kg in CRRT). c. Protein increases reflect: improved clearances; hypercatabolism; and losses that accrue during RRT.
4. Depletion of electrolytes. a. Frequent monitoring in CRRT is important for proper supplementation. In the SLEDD modalities electrolytes should be checked every 4 hours. b. Adjustments in the concentrations of electrolytes can be made in the dialysate and/or total parenteral nutrition (TPN) where applicable, to avoid repeated supplemental infusions.
5. Bleeding and need for continuous anticoagulation (see text).
6. Avoid errors in volume management. a. This is an important issue and daily changes need discussion between intensivist and nephrologist when calculating the new “dose” of RRT and net UF necessary.
7. Errors can occur in the compounding of replacement fluid or dialysate by local hospital pharmacies or in the addition of additives by bedside nursing staf .
8. Errors can occur in the compounding of fluids for CRRT.

Secondly, the process itself: the water in the dialysate, catheter and tubing plastic, and dialyzers are all capable of initiating inflammatory responses. Modifying dialysate water to ultrapure status, for instance can decrease inflammation and morbidity.⁶³ Finally as discussed earlier, better attention to antibiotic dosing is needed.

T irdly, it may be that even with all these RRTs, present clearances are simply inadequate in the severely critically ill patient. Recent data demonstrate eGFR rising up by 40%, and over 130 cc/min in some

critically ill patients.⁶⁴ Critically ill patients may need elevated clearances to help them survive their cata-bolic state, where the uremic toxin burden may be high.¹⁶ RRT modalities at best approach 30 cc/min or stage 4 CKD. Data that more intense RRT does not improve outcomes further support this.¹³ Even with higher-intensity RRT, our attempts may not even begin to provide what is needed.

RRT: FUTURE

Reviewing the shortcomings of present RRT sys-tems prompts possible future research endeavors to optimize present systems. T ese include pharmaco-kinetic studies, improved biocompatible materials, and possibly water purification. Improving monitor-ing accuracy is also needed to minimize electrolyte and hemodynamic deficits.

Care in the design of proper future studies⁶⁵ is also paramount to understand outcomes. Biomarkers of AKI such as cystatin need to be studied to not only assess earlier response but if RRT is necessary. Recog-nition of the important consequences of AKI appears to be at hand and has prompted research in these areas.

TABLE 3 1–5 Outcome benefits.

Cost	^a SLEDD
Elevated ICP	^b CRRT, SLEDD, ^c PD
Hyperkalemia; hyper/hyponatremia	CRRT, SLEDD, PD
Volume control/hemodynamics	CRRT, SLEDD
Mortality	Comparable

^aSLEDD, sustained low-efficiency daily dialysis.
^bCRRT, continuous renal replacement therapy.
^cPD, peritoneal dialysis.

Hematologic Dysfunction in the ICU

John C. Chapin, MD and Maria T. Desancho, MD, MSc

KEY POINTS

- 1 The most common reasons for hematologic consultation in critically ill patients include thrombocytopenia, anemia, and less commonly, evaluation of leukocytosis and thrombocytosis.
- 2 Coagulopathies including severe bleeding and thrombotic disorders are very prevalent in intensive care unit (ICU) patients due to their underlying conditions including liver dysfunction and acquired vitamin K deficiency. Bleeding can occur due to renal insufficiency and the use of antiplatelet agents and anticoagulant therapy.
- 3 Inflammation occurs in sepsis, systemic inflammatory response syndrome, and other critical illnesses, and causes alterations in both hemostasis and fibrinolysis.
- 4 Disseminated intravascular coagulation (DIC) is observed in approximately 50% of patients with sepsis, and is an independent predictor of morbidity and mortality.
- 5 Thrombocytopenia (platelet count $< 150,000/L$) occurs in 15% to 58% of ICU patients and may be due to medications, infections, DIC, thrombotic microangiopathies (thrombotic thrombocytopenic purpura [TTP] and atypical hemolytic uremic syndrome), heparin-induced thrombocytopenia (HIT), catastrophic antiphospholipid syndrome, and immune thrombocytopenic purpura.
- 6 HIT is a clinicopathologic diagnosis that occurs in 1% to 4% of patients on unfractionated heparin (UFH), and less than 1% of patients on low-molecular-weight heparin (LMWH). It is more common in postsurgical patients than medical inpatients and in females.
- 7 Prompt interaction between the intensivist and the hematologist is key to optimize the care of critically ill patients with hematologic dysfunction.

INTRODUCTION

Patients admitted to the ICU have frequent hematologic dysfunction as a result of critical illness leading to multiorgan dysfunction and failure. A hematology consultation is often requested for evaluation of hematologic complications in these critically ill patients. The most common reasons for hematologic consultation include evaluation of cytopenias

mainly thrombocytopenia, anemia, and less commonly, evaluation of leukocytosis and thrombocytosis. Coagulopathies including severe bleeding and thrombotic disorders are very prevalent in the ICU patients due to their underlying conditions. These patients frequently develop DIC or severe coagulopathy secondary to liver dysfunction or acquired vitamin K deficiency. Bleeding can also be seen as

a consequence of renal insufficiency, and the use of antiplatelet agents causing an acquired thrombocytopathy. The administration of anticoagulants in these patients is challenging as the bleeding risk is increased. Hemostasis is frequently disrupted, as these patients often require invasive and/or surgical procedures. Thrombotic complications either venous, arterial, or microvascular are commonly seen as a result of indwelling catheter placement or other invasive procedures, prolonged immobilization, underlying malignancy, autoimmune disorder, or medication related. Frequent exposure to blood products, increases the risk of transfusion reactions including transfusion-related acute lung injury (TRALI) and hemolytic, febrile, and allergic transfusion reactions. In addition dilution coagulopathies are seen in patients who are massively transfused. Prompt interaction between the intensivist and the hematologist is key to optimize the care of these challenging patients.

Overview of Hemostasis

Hemostasis maintains a closed system of vascular integrity and prevents blood loss from injury.¹ The hemostatic response is initiated by injury to endothelial cell surfaces that leads to exposure of tissue factor (TF), collagen, von Willebrand factor (vWF), and fibronectin on the subendothelial matrix. Primary hemostasis consists of platelet adhesion by binding to collagen and vWF on the exposed endothelial surface. Platelets then aggregate via glycoprotein IIb-IIIa receptors, which bind fibrinogen and form platelet thrombi. When activated, platelets release vasoactive, inflammatory, and thrombogenic mediators. For example, ADP binds to the purinergic receptors P2Y₂ and P2Y₁₂ to promote aggregation. Thromboxane A₂ is also synthesized in the platelets by cyclooxygenase (COX) enzymes and stimulates vasoconstriction and platelet aggregation.

Secondary hemostasis is the process of thrombin generation by coagulation proteins, which are classified into extrinsic, intrinsic, and common pathways ([Figure 32–1](#)). The initial step in secondary hemostasis occurs when TF binds to activated factor VII (extrinsic pathway). The intrinsic pathway is composed of factors XII, XI, IX, and VIII, also known as the contact activation pathway.

Both pathways activate thrombin (factor IIa) from prothrombin (factor II) through the prothrombinase complex, which is composed of factors Xa, Va, calcium, and phospholipids. Thrombin generation leads to the conversion of fibrinogen to fibrin, which polymerizes and is cross-linked by factor XIIIa, creating a thrombus.

Thrombin activates fibrinogen, platelets, and acts as its own regulator by activating the natural anticoagulants protein C (PC), protein S (PS), and antithrombin (AT) that in turn inactivate coagulation at multiple steps and limit fibrin deposition (see [Figure 32–1](#)).

Vitamin K, an essential cofactor for the conversion of glutamic acid residues to gamma-carboxyl glutamate (Gla) residues, allows factors II, VII, IX, X, PC, and PS to bind to the surface of plasma membranes and perform their functions. Vitamin K antagonists like warfarin cause multisite blockade of the coagulation cascade by impairing the creation of Gla domains. Fibrinolysis is the process of thrombi dissolution, a necessary step to prevent undesired excess fibrin deposition and pathologic thrombus formation.^{2,3} Plasminogen is activated by tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA) in conjunction with annexin II, which cleave fibrin into fibrin degradation products including d-dimers.

Evaluation of Primary and Secondary Hemostasis

Platelet functional assays and aggregometry measure qualitative defects in platelet hemostasis. These tests include platelet functional assay 100 (PFA-100) and platelet aggregometry ([Table 32–1](#)). PFA-100 testing uses special collagen-epinephrine and collagen-ADP cartridges where in whole blood pass through a chamber and aggregate. If one or both of the cartridge closure times are prolonged, it suggests a qualitative platelet defect. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) cause prolongation of the collagen-epinephrine time. Both tests will be prolonged in von Willebrand disease (vWD), congenital or acquired thrombocytopathies seen in renal and hepatic disease. Platelet aggregation and secretion studies either using whole blood or platelet-rich plasma evaluates specific platelet defects. It should be

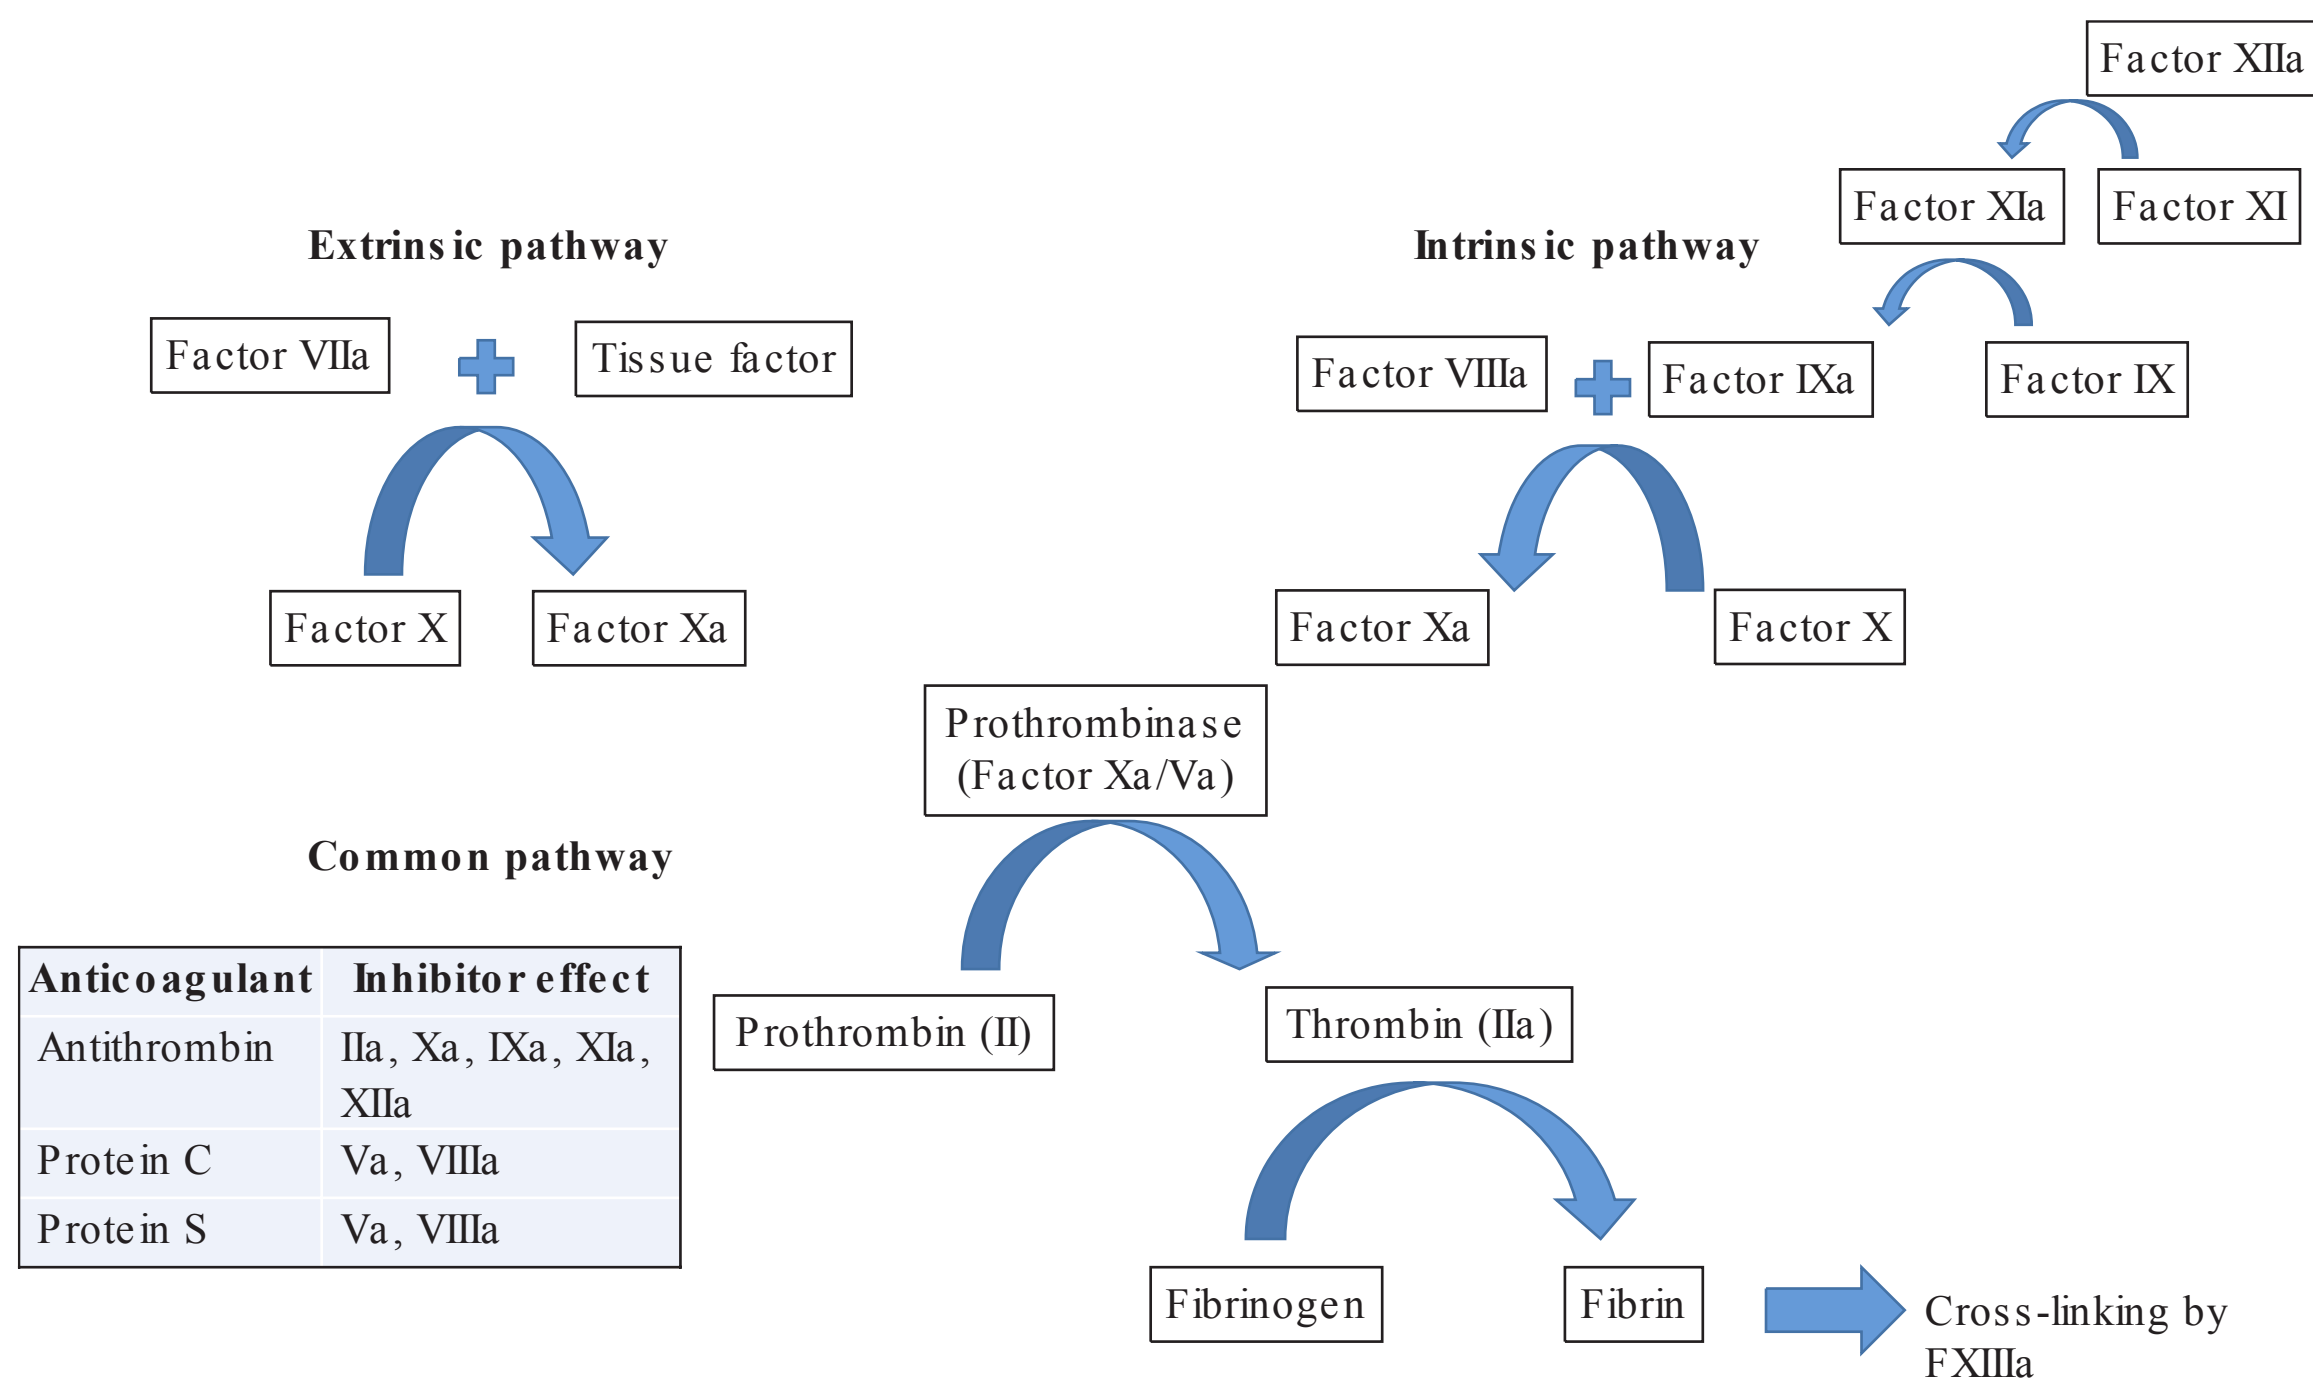

FIGURE 32–1 The coagulation cascade model of hemostasis. The extrinsic pathway is activated by exposure of tissue factor. The intrinsic pathway begins when factor XIIa is activated by contact pathway activators. Both pathways result in the generation of factor Xa and the formation of the prothrombinase complex. Thrombin activates fibrinogen to fibrin, which is cross-linked and polymerizes.

noted that platelet function tests might be abnormal when the platelet count is less than 100,000/L unless the concentrations are adjusted in plasma.

The screening tests of blood coagulation are the prothrombin time (PT) and the activated partial thromboplastin time (aPTT). These tests become prolonged when coagulation factor activities are 20% or less. The PT is used to determine risks of bleeding from defects in the extrinsic and common pathways. The international normalized ratio (INR) is the PT normalized to a pool of known PTs in a population of patients on vitamin K antagonists and adjusted for thromboplastin reagent types. It should be noted that the INR is standardized for bleeding and thrombotic risks for patients on warfarin and does not accurately reflect coagulation dysfunction in liver disease or other coagulopathies.^{4,5}

The aPTT is a test of the intrinsic and common pathways of coagulation. The aPTT is also used to measure therapeutic levels of intravenous

anticoagulants like heparin and direct thrombin inhibitors like argatroban and bivalirudin. When a prolonged PT or aPTT is detected, a variety of diagnoses are implicated and should be related to the patient's clinical presentation and history (Table 32–2). Further evaluation consists on a mixing PT and/or aPTT test that is performed by adding the patient's plasma to a pool of normal plasma in a 1:1 ratio and measuring the PT and/or aPTT immediately and after incubation of 60 to 120 minutes at 37°C. If the clotting time corrects into the normal range upon mixing, this is referred to as an immediate correction. Incubation is performed to detect slow-acting coagulation inhibitors, characteristic of an acquired factor VIII deficiency, which will cause prolongation of the aPTT after initial correction. A failure of the mixing study to correct immediately and after incubation is consistent with the presence of a lupus or lupus-like anticoagulant (LA). A sustained correction is consistent with a

TABLE 32–1 Coagulation tests methodology and diagnostic use.

Thrombin time	Add thrombin to citrated plasma, cleaves fibrinogen to fibrinopeptides A and B	Detects defect in thrombin or fibrinogen, affected by anticoagulation
Reptilase time	Add reptilase to citrated plasma, cleaves fibrinogen to fibrinopeptide A	Detects fibrinogen deficiency, not affected by heparin or other anticoagulants
Dilute Russell viper venom time (DRVVT)	Add RVV to plasma to activate factor X in the presence of phospholipid	Detects presence of a lupus anticoagulant, requires confirmation by addition of excess phospholipids
Euglobulin lysis time	Measure time to clot lysis	Detects increased fibrinolysis, factor XIII deficiency
Ecarin clot time	Add ecarin to citrated plasma + thrombin inhibitor, activates prothrombin	Detects direct thrombin inhibitors, not widely available
Thrombin generation assay	Add thrombin to citrated plasma, measure substrate cleavage	Detects quantitative thrombin activity, interlaboratory variability, research tool
Thromboelastography	Can be performed on whole blood	Detects multiple parameters of hemostasis and fibrinolysis, interlaboratory variability, research tool
Bleeding time ^a	Cutaneous lancet injury, measure time to stop bleeding	Detects in vivo qualitative platelet defect, poor reproducibility
PFA-100 ^a	Platelet function assay for collagen and ADP	Detects mild platelet binding disorders and aspirin exposure, does not detect platelet secretion defects
Platelet aggregometry ^a	Measures platelet aggregation and secretion to multiple agonists	Detects platelet secretion defects and aggregation defects which are agonist-specific, high variability
Verify now ^a	Measures platelet aggregation and response to P2Y12 inhibitors	Detects clopidogrel, prasugrel, ticagrelor, ticlopidine-induced platelet inhibition, interference with inherited platelet disorders and VWD

^aAny test of platelet in whole blood must be performed with platelet counts more than 100,000/L to avoid false-positives from thrombocytopenia.

coagulation factor deficiency. Falsely positive LA is seen in the presence of heparin, direct thrombin, and Xa inhibitors and may be falsely positive when the patient is on warfarin and the INR is supra-therapeutic. Therefore an LA test should not be

TABLE 32–2 Prolonged coagulation tests and diagnosis.

Prolonged PT	Factor VII deficiency, vitamin K antagonist use, vitamin K deficiency, lupus anticoagulant
Prolonged aPTT	Factor deficiency (factors VIII, IX, XI), heparin anticoagulation, argatroban, bivalirudin anticoagulation, lupus anticoagulant
Prolonged PT and aPTT	Factor deficiency (factors II, V, X, fibrinogen), vitamin K deficiency

requested when the patient is receiving these anti-coagulants. Bethesda units (BU) are used to measure inhibitor titers to clotting factors and reflect the strength of inhibitors that are detected on mixing studies. One BU is equivalent to the reciprocal dilution of the patient’s plasma at which 50% of the specific factor activity is inhibited. For example, in the case of acquired hemophilia A, a BU titer of 5 indicates a dilution of 1:5 where 50% of the factor VIIIa activity was inhibited.

Occasionally, a shortened PT or aPTT is observed in critical illness. A shortened PT is the result of an increase in circulating TF after central nervous system (CNS) injury, stroke, or sickle cell crisis. Similarly, inflammation-induced elevations of factor VIII may result in a shortened aPTT. More specific coagulation testing and their indications are described in Table 32–1.

Inflammation in the ICU

Inflammation occurs in sepsis, systemic inflammatory response syndrome, and other critical illnesses, and causes alterations in both hemostasis and fibrinolysis. Platelets are activated and may become prothrombotic in inflammatory states, white cells are more adhesive to vessel walls by expressing vessel adhesion molecules, and toxic degranulation occurs. Oxidative damage as the result of free radical generation causes decreased red cell membrane flexibility and expression of adhesion molecules on the surface of endothelial cells. Hypoxia is also a prothrombotic trigger. Inflammation may worsen anemia as red blood cells are subjected to cytokines and turbulent blood flow, ultimately leading to hemolysis. Inflammatory cytokines also increase expression of TF on the surface of monocytes and in circulating microparticles. Coagulation factors like fibrinogen, factor VIII, and vWF are acute-phase reactants and their levels may increase secondary to inflammation.

Targeting Inflammation

Initial clinical trials to treat sepsis with drotrecogin-alfa (Xigris), a recombinant activated protein C suggested improvement in outcomes in some critically ill patients. However, reevaluation of this agent in the PROWESS-SHOCK trial showed no benefit of drotrecogin-alfa in patients with septic shock and the drug was withdrawn from the market.^{6,7}

Disseminated Intravascular Coagulation

DIC is a consumptive coagulopathy that is frequently encountered in critically ill patients. DIC is observed in approximately 50% of patients with sepsis, and is an independent predictor of morbidity and mortality. Other common etiologies of DIC are shown in Table 32–3. DIC occurs as the result of increased circulating procoagulant factors that lead to high levels of thrombin generation and cytokine activation. Systemic activation of thrombin and platelets causes thrombosis in both small and large vessels. Platelets become activated and then aggregate in response to increased thrombin generation causing progressive thrombocytopenia. As the regulatory proteins of thrombin generation and coagulation are progressively overwhelmed,

the systemic circulation becomes more thrombogenic. Coagulation factors are consumed in diffuse thromboses, leading to organ failure, ischemia, and tissue damage. Deep venous, arterial, and cerebrovascular thromboses also occur. Fibrinogen levels decrease as DIC continues, resulting in a fibrinogen deficiency and increased bleeding tendency.⁸ In severe cases, gangrene and limb ischemia (purpura fulminans) develops. No single test or clinical finding is able to accurately diagnose DIC. The diagnosis must be based on underlying clinical predisposition. A combination of prolonged PT, prolonged aPTT, and thrombocytopenia are suggestive of DIC, as is a decreased level of fibrinogen.⁹ Approximately 50% of patients with DIC will have prolongation of the PT or aPTT at some point during the course of DIC. The aPTT may initially be shortened as a result of inflammatory increases in FVIII and fibrinogen. Elevated fibrin degradation product (FDP) and d-dimer levels indicate increased thrombin and plasmin generation. However, d-dimer is also elevated in the postsurgical state, after trauma, in the setting of deep vein thrombosis and with liver and renal dysfunction. The platelet count is of particular

utility in DIC as thrombocytopenia correlates with thrombin generation.^{9,10} Thrombocytopenia may develop rapidly (within 1-4 hours) of the onset of DIC and is an independent predictor of mortality and length of ICU stay.¹⁰ Once the platelet count reaches a nadir, it suggests stabilization of thrombin generation. A platelet count less than 100,000/L is seen in 50% to 60% of patients with DIC, and counts less than 50,000/L are seen in approximately 10% of patients. Several scoring systems for DIC have been developed, and are dependent on clinical presentation and laboratory values. The International Society for Thrombosis and Haemostasis (ISTH) score for overt DIC is shown in Table 32–4, and has a specificity of 91% and a sensitivity of 97%.¹¹ This score is meant to be calculated daily based on serial laboratory measurements and guide clinicians to the improvement or worsening of their patients. The scoring system should be used only when the patient’s clinical history is compatible with DIC.

The cornerstone of treating DIC is correction of the underlying cause. Platelets and plasma

transfusions should be used for bleeding patients and not solely to correct laboratory values. In the setting of bleeding, plasma should be administered at 15 to 20 mL/kg, and platelets should be transfused to over 50,000/L. Hypofibrinogenemia (fibrinogen concentration 100 mg/L) should be corrected by 10 donor pools (2 units) of cryoprecipitate or 3 g of a fibrinogen concentrate. Antifibrinolytics (tranexamic acid, ε-aminocaproic acid), activated prothrombin complex concentrates (FEIBA) and recombinant factor VIIa (rFVIIa) should be avoided, as they can worsen thrombosis. Anticoagulation should not be withheld in patients with DIC unless the bleeding risk is significant. DIC patients without bleeding should have routine pharmacologic thromboprophylaxis.

Bleeding

Bleeding disorders occur in critically ill patients and their etiology is usually multifactorial. Bleeding is seen as a consequence of thrombocytopenia and/or thrombocytopathies or is related to acquired coagulation factor deficiencies. Thrombocytopenia is commonly drug related, or caused by severe liver disease, or DIC. Thrombocytopathies are secondary to the use of antiplatelet agents such as aspirin, NSAID, and P2Y12 inhibitors, also seen with liver and renal dysfunction and in patients with congenital thrombocytopathies or vWD. The bleeding pattern may point to a specific etiology. For example, patients with severe thrombocytopenia, thrombocytopathies, and vWF defects present with mucocutaneous bleeding. Conversely patients with severe inherited coagulation factor defects (eg, factors VIII and IX) present with hemarthrosis, muscle, and soft tissue bleeding. Interestingly, the bleeding pattern in patients with acquired factor VIII inhibitors is also mucocutaneous. Some patients may have no known personal or family history of bleeding disorders, but hemostatic challenges that occur in the hospital setting (biopsies, surgeries, placement of intravascular devices) may unmask mild congenital bleeding disorders such as thrombocytopathies, factor XI deficiency, and fibrinolytic defects.

A diagnostic approach to the bleeding patient should include thorough examination of patient’s skin, flank, hips, and mucosal surfaces for petechiae, ecchymoses, or hematomas. Inspection of the digits

TABLE 32–4 ISTH DIC scoring system for overt DIC.

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC? ^a If yes, proceed. If no, do not use this algorithm
2. Order global coagulation tests (platelet count, PT, fibrinogen, soluble fibrin monomers/fibrin degradation products/d-dimer)
3. Score global coagulation test results Platelet count (> 100 = 0, < 100 = 1, < 50 = 2) Elevated fibrin-related marker (eg, soluble fibrin monomers/fibrin degradation products /d-dimer; no increase = 0, moderate increase = 2, strong increase = 3) Prolonged PT (< 3 s = 0, > 3 but < 6 s = 1, > 6 s = 2) Fibrinogen level (> 1 g/L = 0, < 1 g/L = 1)

*e.g. bacterial sepsis, trauma (esp CNS), fat embolism, burn injury, pancreatitis, malignancies (esp acute *e.g.
^aFor example, bacterial sepsis, trauma (esp CNS), fat embolism, burn injury, pancreatitis, malignancies (esp acute promyelocytic leukemia), obstetric complications (preeclampsia, placental abruption, amniotic fluid embolism, intrauterine fetal demise), vascular aneurysms, hemangiomas (eg, Kasabach-Merritt syndrome), advanced liver failure, illicit drug use, snake bites, severe transfusion reactions, transplant organ rejection.

may reveal evidence of ischemia or embolism that reflects a systemic disorder.

In addition careful inspection of chest and endotracheal tubes, urinary catheters, surgical drains, and suction devices should be carefully performed. A high suspicion for local wound complications should be maintained, especially if the patient is within 48 hours of an invasive or surgical procedure. Hemoccult testing is useful in assessment of gastrointestinal bleeding.

The Initial laboratory evaluation should include a complete blood count, PT, aPTT, and fibrinogen. A manual platelet count should be performed by manual examination of the peripheral blood smear if thrombocytopenia is reported in a patient with no signs of bleeding. Pseudothrombocytopenia is a laboratory artifact characterized by platelet aggregation in response to ethylenediaminetetraacetic acid (EDTA), heparin, or citrate, and should be excluded early in the diagnostic evaluation. If large clumps of platelets are observed on the peripheral smear, the platelet count should be repeated using a different anticoagulant tube or by peripheral finger stick to obtain a more accurate platelet count.

Acute management of a bleeding includes discontinuation of all medications that contribute to bleeding, evaluation of a bleeding site, and reversal of hemostatic abnormalities. In addition to local cauterization or compression when a bleeding site is identified, platelets are used for patients with severe thrombocytopenia or thrombocytopathy. Vitamin K is administered for correction of acquired vitamin K deficiency either due to vitamin K antagonists or other acquired etiologies of vitamin K deficiency. Vitamin K is administered at 10 mg intravenously over 15 to 30 minutes and takes effect within 6 to 12 hours. Plasma is used to correct coagulopathy secondary to liver disease and for rapid reversal or vitamin K antagonists. Plasma is infused at doses of 10 to 15 mL/kg given every 6 hours until hemostasis is achieved. Plasma contains approximately 0.7 to 1 unit/mL of clotting factor activity and 1 to 2 mg/unit of fibrinogen. Cryoprecipitate is a protein fraction of plasma, enriched in factor VIII, vWF, fibrinogen, fibronectin, and factor XIII. One unit of cryoprecipitate is obtained from 1 unit of plasma. Cryoprecipitate is indicated to correct hypofibrinogenemia in patients with DIC presenting with

bleeding and it is also used in managing dysfibrinogenemia or hypofibrinogenemia in patients with severe liver disease. Cryoprecipitate is administered at 1 unit per 5 kg of body weight, with the goal of increasing fibrinogen to greater than 100 mg/dL.

If excessive fibrinolysis is suspected, antifibrinolytic lysine analogues should be administered. These drugs act as competitive analogues of fibrin and bind plasminogen. Tranexamic acid is given orally at 25 mg/kg or 10 mg/kg IV every 8 hours, ε-aminocaproic acid is given at 50 mg/kg every 6 hours orally or IV 5 g bolus followed by 1 g/h continuous infusion. Tranexamic acid must be dose reduced in patients with renal failure. Both of these agents should be avoided in DIC and in genitourinary bleeding, where the risk for thrombosis is significant. Tranexamic acid has been shown to reduce bleeding and death related to bleeding if administered within 3 hours.

Transfusions of red blood cells should be restricted to actively bleeding patients and the decision to transfuse blood products must be carefully weighed against the risk of transfusion-related fever, circulatory overload, lung injury, and alloimmunization.¹²

Specific Bleeding Diagnoses

Acquired Hemophilia A

Acquired hemophilia A is a rare disorder with an incidence of 1 in 1 million, where patients develop autoantibodies to endogenous factor VIII. This disease is characterized by ecchymoses, soft tissue hematomas, and petechiae, but CNS bleeding can develop. Predisposing factors are poorly understood. In some cases, the identified trigger is pregnancy, new-onset malignancy, and autoimmune disorders and is more commonly seen in the elderly. In nearly 50% of cases, it appears to be idiopathic. Acquired hemophilia A is diagnosed by a prolonged aPTT with initial partial correction by a mixing study, which prolongs after incubation. Treatment should be aimed at controlling bleeding and eradicating the inhibitor. Bleeding is managed with activated prothrombinase complex concentrates (FEIBA at 60-100 IU/kg every 12-24 hours) or rFVIIa (90-100 µg/kg given every 2-3 hours). Simultaneously, treatment to eradicate the inhibitor is initiated with either high-dose prednisone (1 mg/kg) and cyclophosphamide (2 mg/kg daily) or rituximab

(375 mg/m²) administered as 4 weekly doses. The inhibitor is eradicated in approximately half of all patients but may take several months, and careful observation for bleeding and complications of immunosuppression is warranted during this time.¹³

Congenital Bleeding Disorders

Congenital bleeding disorders include hemophilia A and B, vWD, and other factor deficiencies. In the presence of a known coagulopathy, factor-specific assays should be sent to determine the baseline activity. Severe hemophilia patients should be maintained on a factor replacement prophylaxis strategy, consisting of factor VIII products administered at doses of 25 to 35 IU/kg every other day (hemophilia A), or factor IX doses of 40 to 60 IU/kg twice a week (hemophilia B). One specific concern with hemophilia B replacement products is the development of anaphylaxis in 5% of patients. Prior to invasive procedures or surgeries, factor VIII or IX activity should be elevated to approximately 100% by the administration of factor-specific products. In mild hemophilia A and vWD, desmopressin acetate (DDAVP) may be administered by IV (0.3 µg/kg) or intranasally 150 µg (1 puff in each nostril) to increase vWF and FVIII activity by 2 to 5 times the baseline within 15 to 30 minutes. Severe vWD patients may require vWF-containing factor replacement (Humate P, Wilate, Alphanate). Hemophilia patients with inhibitors are treated with FEIBA or rFVIIa. New longer acting hemophilia concentrates are now available that can prolong the detectable activity of factors VIII and FIX. (ref 36)

Liver Disease and Coagulation

The liver is the source of synthesis of most coagulation factors. Clues to hepatic dysfunction as the cause of a coagulopathy are a decreased albumin, prolonged PT, or known cirrhosis. Liver coagulopathy may present as both bleeding and clotting disorders. In addition to having reduced procoagulant factors, liver dysfunction results in decreased synthesis of natural anticoagulants namely protein C, S, and antithrombin and impaired fibrinolysis, which can lead to a prothrombotic state. A patient with bleeding should receive plasma and cryoprecipitate, and a patient with thrombosis should be anticoagulated, even in the setting of a prolonged PT.⁵

Aside from liver transplantation, there is no cure for hepatic coagulopathies.

Vitamin K Deficiency

Vitamin K is a fat-soluble vitamin that exists in 2 important forms: vitamin K₁, found in green leafy vegetables, and vitamin K₂, is synthesized by normal gut flora. Antibiotic exposure alters the natural gut flora, decreasing the reserve of bacteria-producing vitamin K. Deficiencies of vitamin K occur in the hospital when the diet is not well balanced or the patient is on broad-spectrum antibiotics for over a week.¹⁴ Other causes are poor oral intake, impaired absorption of fat-soluble vitamins (occurring in pancreatitis and cholestyramine treatment), and the use of nasogastric suction. Vitamin K deficiency leads to gastrointestinal, and postsurgical hemorrhage. Excessive bleeding from needle punctures, and intramuscular hematomas can also be noted. Both the PT and aPTT are prolonged as in DIC, but in vitamin K deficiency plasma activity levels of factors II, VII, IX, and X are less than 50%, while fibrinogen, factor V, and VIII are normal. d-Dimer is also normal in vitamin K deficiency. A 1:1 mixing study should be completely correct in this setting. If a vitamin K deficiency is suspected, repletion with 5 to 10 mg of vitamin K should begin by intravenous administration. Correction of the PT should occur 6 to 12 hours after vitamin K administration. Critically ill patients at risk for coagulopathies from vitamin K deficiency should be supplemented by administering 5 mg of vitamin K 2 or 3 times weekly, either orally or intravenously.¹⁴

Anticoagulant Overdose

Overdosing of anticoagulants can result in serious bleeding complications in critically ill patients. Intravenous and subcutaneous UFHs are preferable to oral anticoagulation in the ICU because of their short half-life and reversibility ([Table 32–5](#)). If a bleed occurs, heparin must be stopped immediately. Heparin is reversed by administering protamine sulfate 1 mg per 100 units of heparin every 2 to 8 hours, to a maximum dose of 50 mg in 24 hours. If there is an ongoing need for anticoagulation, the heparin should be restarted without bolus at a reduced dose once the bleeding has been controlled. Protamine is less effective at reversing LMWHs and is not effective in reversing fondaparinux.

TABLE 32–5 Anticoagulation reversal.

Anticoagulant	Half-Life (hours)	Reversal Agents
Vitamin K antagonists	20-60	Vitamin K 10 mg IV or po, plasma, 4-factor PCCs (eg, Kcentra)
Unfractionated heparin (IV or sq)	1-3	Protamine 1 mg per 100 units of UFH, do not exceed 50 mg
Low-molecular-weight heparin	4-5	Last dose 0-8 h: protamine 1 mg per 100 units of heparin, do not exceed 50 mg, last dose 8-12 h: protamine 0.5 mg per 100 units of heparin, last dose > 12 h, no protamine indicated
Dabigatran ¹	12-14	Local compression, dialysis, activated charcoal if within 2 h, transfusion support, FEIBA, rFVIIa, idaruciumab (Praxbind)
Edoxaban	10-14	Local compression, activated charcoal if within 2-3 h, transfusion support, PCCs, rFVIIa, FEIBA
Rivaroxaban ^{a2}	5-9	Local compression, activated charcoal if within 2-3 h, transfusion support, PCCs, rFVIIa, FEIBA
Fondaparinux ^a	17-21	Local compression, transfusion support, PCCs, rVIIa, FEIBA
Apixaban ^a	9-14	Local compression, activated charcoal if within 1 h, transfusion support, PCCs, rFVIIa, FEIBA
Argatroban ^a	1-3	Local compression, transfusion support, PCCs, rFVIIa, FEIBA
Bivalirudin ^a	25 min	Local compression, transfusion support, PCCs, rFVIIa, FEIBA

^aTo date there are no effective reversal agents for these drugs.

1. Dialysis eliminates 60% of dabigatran from circulation.

2. Doses rFVIIa 45-90 µg/kg, FEIBA 25-50 IU/kg, PCCs 50 IU/kg.

Warfarin-induced bleeding can be mild or severe. However, supratherapeutic INRs may not need aggressive reversal in the absence of bleeding. Patients with a supratherapeutic INR without bleeding should have their warfarin held and their INR monitored daily until it reaches the therapeutic range. Vitamin K reversal should be given when the INR is 10 or greater in the absence of bleeding. Any bleeding that occurs while on warfarin should be reversed with vitamin K, regardless of the INR. An intracranial bleed should be treated immediately with vitamin K (10 mg IV), plasma (25-35 mL/kg), and 4 factors prothrombin complex concentrate (PCCs) like Kcentra. Kcentra contains factors II, VII, IX, X, PC, and PS, which is, concentrated 25-fold, equivalent to 2 L of plasma. As Kcentra contains heparin, it is contraindicated in patients with HIT. Kcentra is administered over 10 to 15 minutes at doses of 25 to 50 IU/kg, and normalizes the INR within 30 to 60 minutes of administration.¹⁵

The Food and Drug Administration (FDA) approved idarucizumab (Praxbind), a monoclonal Fab fragment for reversal of dabigatran, in 2015 based on the results of the RE-VERSE AD trial (Pollack N Engl J Med 2015, PMID: 26095746). This drug is administered by IV injection at a single dose of 5g. Repeat doses can be considered in consultation with a hematologist and pharmacist. Development of reversal agents for anti-Xa inhibitors are currently in development, including the recombinant protein factor Xa mimic andexanet (Segal DM N Engl J Med 2015; PMID 26559317). In the event of bleeding, besides discontinuation of the offending agent, evaluation for the source of bleeding and supportive therapy including transfusion of red blood cells, activated charcoal (25 g) can be administered orally if ingestion of dabigatran was within 3 hours and within 2 to 3 hours after ingestion of rivaroxaban and apixaban, particularly if intentional overdose. In addition, approximately 60% of dabigatran can

be removed by hemodialysis over 2 to 3 hours. Activated prothrombin complex concentrates (FEIBA) 25 units/kg can be considered for dabigatran-related life-threatening bleeds, and rFVIIa has been used as well to control bleeding.¹⁶ Kcentra at a dose of 50 units/kg can be considered for life-threatening bleeds related to rivaroxaban and apixaban. Plasma does not reverse dabigatran, rivaroxaban, or apixaban bleeds, thus is not recommended for reversal. Platelet transfusions are used if the patient was using concomitant antiplatelet agents.

Acquired von Willebrand Disease

Acquired vWD generally manifests as mucocutaneous bleeding. Different mechanisms are responsible for the loss of vWF multimers in acquired vWD, and this disease should be suspected in patients with myeloproliferative neoplasias, plasma cell dyscrasias, hypothyroidism, lymphoproliferative disorders, and solid tumors. Acquired vWD also result from flow obstructions and increased shear that occurs in hypertrophic cardiomyopathy, aortic valve stenosis, and ventricular assist devices. Valve-induced acquired vWD can present with gastrointestinal bleeding, also known as Heyde syndrome. Decreased vWF antigen and loss of high-molecular-weight vWF multimers are suggestive of acquired vWD. Management of bleeding involves using DDAVP or vWF concentrates, but acquired vWD will only resolve after correction of the underlying disorder.¹⁷ Caution must be exercised with DDAVP administration, as patients may develop hypotension, flushing, and fluid retention. Fluid should be restricted to maintenance rate for 24 hours, and electrolytes should to be monitored every 6 to 8 hours. DDAVP should not be administered for more than 3 days because of the development of tachyphylaxis.

Hemodilution

Critically ill patients frequently are exposed to very high volumes of crystalloid and colloid for volume resuscitation and administration of blood products. The resultant volume changes may affect blood count measurements and cause a dilution in hemoglobin, platelets, and coagulation factors. Prior to evaluation for coagulopathy, these tests should be repeated and drawn peripherally, or of lines that are not receiving fluids or medications. Prior studies

suggest the amount of crystalloid fluid needed to cause true hemodilution is significant, usually from several liters of normal saline given as bolus dosing.¹⁸⁻²⁰ Maintenance fluids alone are insufficient to cause dilution. A recent and more clinical relevant definition of massive bleeding patient proposed by Savage et al refers to patients transfused with greater than 3 units of RBCs in any 60-minute period (within 24 hours of admission). This new definition includes a clinically relevant rate of transfusion and includes the majority of patients who rapidly exsanguinate.²¹ The Trauma Outcomes Group collected data from 466 massive transfusion patients from 16 level 1 centers from 2005 to 2006 across the United States. This study demonstrated that outcomes were improved with a more balanced ratio of at least 1:1:2 of plasma:platelets:RBC. Subsequently, the Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study was performed at 10 level 1 trauma centers where in-house 24/7 research assistants recorded the sequence and timing of all infused fluids in bleeding trauma patients in 2009 to 2010. A balanced use of plasma early in resuscitation was associated with improved early survival. The median time to hemorrhagic death was 2.6 hours, whereas platelets were infused at a median time of 2.7 hours and 30% of patients who died from hemorrhage never received any platelets. An ongoing prospective randomized clinical trial at 12 centers in North America Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial (www.clinicaltrials.gov identifier: NCT01545232) compares a 1:1:1 ratio of plasma:platelets:RBCs with a 1:1:2 ratio in patients predicted to receive a massive transfusion.²² The colloid solution hydroxyethyl starch has also been associated with both a dilutional coagulopathy and an acquired vWD.²³

Using Recombinant Factor VIIa in Critical Illness

The use of rFVIIa has been used in ICU patients to control bleeding. This short-acting activated coagulation factor binds directly to activated platelets and improves systemic hemostasis. It is currently approved for use in hemophilia patients with inhibitors and in patients with congenital factor VII deficiency. The advantages of rFVIIa are rapid onset of hemostasis and minimal volume. However, this drug must be used with caution

in patients who do not have congenital coagulopathies, especially in patients over the age of 65, where the risk of arterial thrombotic events was 5.5%.²⁴

Acquired Platelet Dysfunction

Acquired platelet dysfunction may occur as a result of medication use (nonsteroidal anti-inflammatory agents, aspirin, clopidogrel, prasugrel, ticagrelor) or uremia. Uremic platelet dysfunction is multifactorial, resulting from decreased aggregation, displacement from the endothelium, and impaired secretion of granules. Dialysis is used to correct platelet dysfunction. Although desmopressin can shorten the skin-bleeding time in patients with uremia, the use of recombinant erythropoietin stimulating agents has made this abnormality of hemostasis much less frequent than it was previously. The beneficial effect of erythropoietin on hemostasis is based on the increase in red-cell mass, which affects the blood-fluid dynamics, leading to a more intense interaction between circulating platelets and the vessel wall.²⁵ Conjugated estrogens may also be used to correct uremic dysfunction, given at 0.6 mg/kg IV over 30 to 40 minutes for 5 days.

Multiple antiplatelet agents are used in cardiac patients, including aspirin, ibuprofen, ticlopidine, clopidogrel, prasugrel, ticagrelor, dipyridamole, abciximab, tirofiban, eptifibatide, and vorapaxar (Table 32–6). All of these medications create a qualitative platelet dysfunction and can cause bleeding. If bleeding develops, they should be held while the patient receives platelet transfusions to restore the pool of functional platelets.

Thrombocytopenias

Platelets are synthesized from megakaryocytes in the bone marrow by stimulation of the thrombopoietin receptor by thrombopoietin and other cytokines. The megakaryocytes then release platelets into circulation, which are ultimately cleared in the spleen and liver. Splenomegaly or platelet-specific antibody binding may result in increased clearance of platelets and result in thrombocytopenia, defined as a platelet count less than 150,000/L. Thrombocytopenia occurs in 15% to 58% of ICU patients. In medical ICU patients and in septic patients, platelet counts may decrease within 3 to 5 days of admission, dropping to levels 40% to 90% below baseline. Persistent

TABLE 32–6 Antiplatelet agents.

	Half-life	Mechanism
Aspirin	3 h	Irreversible inhibition of COX-2, decreased thromboxane synthesis
NSAIDs (eg, ibuprofen)	1.8-2 h	Reversible COX-2 inhibition
Clopidogrel	7-8 h	ADP P2Y ₁₂ receptor inhibitor
Prasugrel	7-8 h	ADP P2Y ₁₂ receptor inhibitor
Ticlopidine	12 h	ADP P2Y ₁₂ receptor inhibitor
Ticagrelor	7-8 h	ADP P2Y ₁₂ receptor inhibitor
Abciximab	10-30 min	GP IIb-IIIa inhibitor
Tirofiban	2 h	GP IIb-IIIa inhibitor
Eptifibatide	2.5 h	GP IIb-IIIa inhibitor
Aggrenox (aspirin and dipyridamole)	3 h	Irreversible COX-2 inhibitor & thromboxane receptor inhibitor, Vasodilator
Voraxapar	5-13 days	PAR-1 inhibitor

thrombocytopenia at day 14 predicts increased mortality, irrespective of an identified etiology.²⁶ In the absence of thrombotic disease, platelet transfusions may be used to prevent or correct bleeding.²⁷

When the platelet count falls below 50,000/L, patients are at an increased risk of bleeding from procedures. Furthermore, patients may bleed spontaneously when the platelet count drops below 10,000/L. The differential is broad for thrombocytopenia in critical illness, as numerous medications, infections, and concomitant illnesses can be implicated. However, decreases in the platelet count can also be manifestations of severe thrombotic diseases. A diagnostic strategy must take the clinical scenario into consideration. Platelet counts under 100,000/L are associated with increased 30-day mortality and disturbed immune responses to sepsis in critically ill patients.

Initially, the most important diseases to consider and diagnose are the thrombotic microangiopathies

(TTP and atypical hemolytic uremic syndrome), HIT, catastrophic antiphospholipid syndrome, and immune thrombocytopenic purpura (ITP). These disorders can be fatal if not immediately diagnosed and treated. After these disorders have been evaluated and ruled out, a more detailed review of causes of thrombocytopenia can be accomplished. Disseminated intravascular coagulation should always be considered as the cause of thrombocytopenia in a patient with sepsis, prolonged PT, elevated d-dimer, and low fibrinogen.

Thrombotic Microangiopathies

Thrombotic microangiopathies (TMA) are characterized by microvascular injury to endothelial cells, which can be provoked by infection, inflammation, drugs, and other factors. These injuries promote endothelial cell injury, platelet aggregation, and hemolysis. Inhibition of the vWF-cleaving protease ADAMTS13 is implicated in the pathology of some types of TMAs. The accumulation of ultra-large vWF multimers causes microvascular thrombi that result in multiple organ failure and dialysis dependence. Rapid recognition and treatment of TMAs is essential, as the mortality can approach 90%. Two important TMAs that must be distinguished acutely are atypical hemolytic uremic syndrome (aHUS) and TTP. Differentiating TTP from aHUS is difficult since the 2 diseases have overlapping manifestations. Higher platelet counts and worse degrees of renal failure are associated with aHUS, whereas platelet counts will almost invariably be low ($< 40,000$) in TTP and only mild renal failure is seen.²⁴

The initial evaluation of TMAs should include review of a peripheral smear to confirm decreased platelet count and to identify schistocytes. Markers of hemolysis should be requested including lactate dehydrogenase (LDH), haptoglobin, and a direct antiglobulin test. Stool antigens to evaluate for shiga toxins, like O157:H7 and ADAMTS13 activity should be sent prior to treatments. Undetectable ADAMTS13 activity may indicate either a congenital absence of ADAMTS13 caused by mutation of the ADAMTS13 gene (Upshaw-Schulman syndrome), or the presence of an acquired anti-ADAMTS13 IgG inhibitor. Liver disease, vasculopathies, and peripheral artery disease may also have an ADAMTS13 deficiency, and caution should be used in interpreting these results of such patients.²⁸

Plasma exchange restores ADAMTS13 activity in the majority of TTP patients.²⁹ If plasma exchange is not available, simple plasma transfusions should be initiated at doses of 30 mL/kg. If a response to plasma exchange is not seen within approximately 20 exchange sessions or 45 L of plasma, an alternate diagnosis should be considered, including aHUS. Treatment of refractory TTP is less effective and no current standard exists. Second-line therapies include immunosuppression with rituximab, vincristine, mycophenolate, cyclosporine, bortezomib, and splenectomy. Rituximab (375 mg/m²) for 4 weekly doses has been used successfully to induce remission in patients with persistently low ADAMTS13 activity despite plasma exchange.³⁰

aHUS is a TMA that presents like TTP, but ADAMTS13 activity may be normal. This syndrome is caused by complement protein mutations resulting in hyperactivation of the complement system. The anticomplement C5a antibody eculizumab is approved to treat aHUS with an initial dose of 900 mg IV weekly for 4 weeks, followed by maintenance dosing of 1200 mg every 2 weeks. Prior to eculizumab treatment, it is important to ensure the patient is vaccinated against *Neisseria meningitidis* or covered with antibacterial prophylaxis for the duration of treatment. Clinical and hematologic improvement is usually seen within 1 to 2 weeks.²⁸

Heparin-induced Thrombocytopenia

HIT is a diagnosis not to be missed in a hospitalized patient with new-onset thrombocytopenia. The formation of HIT antibodies occurs when heparin binds to platelet factor 4 and causes a rapid prothrombotic antibody reaction by activating platelet FcγIIaR receptors and increasing thrombin generation. The severity of thrombotic disease in HIT cannot be underestimated. HIT occurs in 1% to 4% of patients on UFH, and fewer than 1% of patients on LMWH, and is more common in postsurgical patients than medical inpatients and in females compared to males.³¹ HIT is a clinicopathologic diagnosis. The first step in evaluation is calculating the 4T score by using the clinical prediction rule (Table 32–7). A low score effectively excludes HIT, and no further workup is needed. If the score is intermediate or high, heparin products, including heparin flushes, and catheters coated with heparin

TABLE 32–7 HIT 4T score.

Parameter	2 points	1 point	0 point
Thrombocytopenia	Platelet count > 50% of baseline and nadir > 20,000/L	Platelet count 30%-50% of baseline or nadir 10-19,000/L	Platelet count < 30% of baseline or < 10,000/L
Timing of platelet count fall	5-14 d after heparin exposure or < 1 d if heparin exposure within 30 d	5-14 d with missing data points, or onset after day 14, or < 1 d with prior exposure to heparin 30-100 d prior	Platelet count fall < 4 d without heparin exposure
Thrombosis	New thrombosis, skin necrosis at heparin site, anaphylaxis to heparin after IV bolus	Progressive or recurrent thrombosis, erythematous skin lesions, suspected thrombosis	None
Other causes of thrombocytopenia	None	Possible	Definite

High probability 6-8 points, intermediate probability 4-5 points, low probability 0-3 points.

Reproduced with permission from Lo GK, Juhl D, Warkentin TE, et al: Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings, *J Thromb Haemost*. 2006 Apr;4(4):759-765.

should be discontinued immediately and the patient should be initiated on an alternate nonheparin anticoagulant. Both the heparin antibody ELISA assays and the serotonin release assay (SRA) test should be sent at presentation. If the antibody test is negative but the clinical prediction score remains high, the patient should remain on heparin-free anticoagulant until the SRA is reported. If the SRA is negative, this effectively rules out HIT and heparin can be resumed. If both tests are positive, the patient should remain on an alternate anticoagulant until the platelet count recovers. The patient may be transitioned to warfarin when the platelet count is over 150,000/L. Argatroban, dosed intravenously at 2 µg/kg/min to an aPTT goal of 1.5 to 3 times baseline, is the only anticoagulant currently approved for treatment of HIT in the USA. Dosing needs to be reduced to 25% (0.5 µg/kg/min) of the indicated dose in case of hepatic insufficiency. In a retrospective analysis of 12 ICU patients with multiple organ dysfunction syndrome (MODS) treated with argatroban for suspected or diagnosed HIT, the mean argatroban dose was significantly lower in patients with hepatic insufficiency compared with patients without hepatic impairment (0.10 ± 0.06 µg/kg/min versus 0.31 ± 0.14 µg/kg/min).³²

Immune Thrombocytopenic Purpura

ITP is characterized by isolated thrombocytopenia often occurring in the absence of identifiable and

specific triggers. ITP is caused by autoantibody-mediated clearance of platelets. The thrombocytopenia is usually severe, with platelet counts often less than 10,000/L. Physical examination may reveal petechiae on the soft palate and the extremities. The peripheral smear may reveal large platelets, which result from the egress of immature platelets from the bone marrow to compensate for platelet destruction. The most feared clinical complication of ITP is intracranial hemorrhage. Secondary causes of ITP, including HIV, hepatitis C, and autoimmune diseases like systemic lupus erythematosus (SLE) should be identified and treated. The first line of treatment in severe ITP is glucocorticoids (prednisone 1 mg/kg daily), intravenous immunoglobulins (IVIg) 1 g/kg given over 1 to 2 days or anti-D for Rh-positive, nonsplenectomized individuals. Treatment options of patients who are unresponsive to or relapse after initial corticosteroid therapies include, rituximab, and the thrombopoietin receptor mimetics romiplostim and eltrombopag. Splenectomy remains a mainstay of therapy in providing sustained remission rates in patients with ITP, although long-term remissions have been attained with Rituximab and other immunosuppressive agents. However, infection and thrombosis remain long-term risks.³³

Medication-related Thrombocytopenia

Drug-induced thrombocytopenia occurs by a variety of mechanisms including direct bone marrow

damage and immune-mediated destruction.³⁴ The bleeding rate is approximately 9% secondary to drug-induced thrombocytopenia and is related to the degree of thrombocytopenia. Nonimmune causes are the result of drug toxins on the bone marrow in patients receiving antineoplastic drugs, antivirals, ethanol, and thiazide diuretics that develop slowly over several weeks of exposure. Immune-mediated thrombocytopenia develops within 14 days, and within 1 to 3 days if the patient had been previously exposed to this drug. The causes of drug-induced immune-mediated thrombocytopenia are multiple and are related to the interaction of the drug, the antibody, and the platelet. Penicillin and cephalosporin drugs act as haptens to initiate an immune response. Quinine and related drugs act as binding agents for platelets and antibodies. Tirofiban, eptifibatide, and abciximab bind directly to GP IIb-IIIa. Gold and procainamide induce the production of platelet-specific autoantibodies. The diagnosis of drug-induced thrombocytopenia should start with the timing of thrombocytopenia and duration of exposure to the medication, with careful notation of the platelet trends. This trend will indicate the trajectory of thrombocytopenia. An excellent resource for reports of drug-induced thrombocytopenia and a grading system is available at www.ouhsc.edu/platelets.

It is prudent to suspect a drug-induced thrombocytopenia after exposures of approximately 9 to 10 days (exceptions noted below). Platelet counts may be severe in some cases, resembling ITP. Improvement is seen after 10 to 14 days of discontinuing the offending medication, but can take up to several months. In severe thrombocytopenia with bleeding, stress doses of prednisone (1 mg/kg) and platelet transfusions should be used in conjunction with stopping the offending drug. Bleeding will resolve in 1 to 2 days after discontinuation of the drug, even though improvements in platelet counts may take longer. In the case that a mild thrombocytopenia develops without bleeding, careful risk-benefit assessment should be made as to the indication for the drug compared to the risk for bleeding.

Posttransfusion Purpura

Posttransfusion purpura occurs as a thrombocytopenia that develops 7 to 14 days after blood

transfusions, often in postpartum women. These women had been preimmunized during pregnancy against a platelet antigen (HPA-1a). When they receive blood products this increases the production of alloantibodies that binds to and clears their platelets, promoting a platelet transfusion-refractory state. This disorder presents with patients having purpura or petechiae, platelet counts are often less than 10,000/L. Platelet clearance should be measured to determine appropriate response to platelet transfusions as follows:

Corrected Count Increment (CCI): (platelet count posttransfusion – platelet count pretransfusion) \times (body surface area)/(number of platelet units transfused $\times 10^{11}$). If the CCI is normal after 1 hour but decreased at 24 hours this suggests a nonimmune mechanism.

If CCIs at 1 hour and 24 hours are less than 7500, the patient is considered platelet refractory and human leukocyte antigen (HLA)-matched platelet transfusions should be considered. Acute bleeding from posttransfusion purpura is treated similarly to ITP, and first-line therapy should be IVIg 1 g/kg for 2 days.

Postsurgery Thrombocytopenia

Platelet counts decline to a nadir within 1 to 4 days after cardiac, vascular, abdominal, or orthopedic surgery as a result of tissue trauma and blood loss, which lead to platelet consumption. Platelet counts should begin to increase after day 4 and reach presurgery levels usually between 5 and 7 days postoperation and may continue to increase for 10 days as a result of reactive thrombocytosis before return to baseline by day 14.

Thrombocytosis

Elevated platelet counts ($> 450,000/L$) may be seen in the ICU patient. Thrombocytosis should be divided into primary and secondary causes. Elevated platelet counts may occur as a result of myeloproliferative neoplasms including essential thrombocythemia (ET) and polycythemia vera (PV). JAK2 mutations in V617F, exon 12 and exon 13 occur in greater than 95% of PV and 50% of ET patients. Myeloproliferative neoplasms are thrombotic risk factors, especially in patients older than 60 years with prior thrombosis

and underlying cardiovascular risk factors. Significant elevation of platelet counts more than 1.5 million may also present with a bleeding diathesis secondary to acquired thrombocytopathy or acquired vWD. Symptomatic patients with elevated platelet counts may benefit from treatment with plateletpheresis and cytoreduction with hydroxyurea, interferon, or anagrelide. Low-dose aspirin 81 mg may be used as primary prevention of thrombosis in some patients without another indication for anticoagulation.³⁵ Secondary thrombocytosis may result from prior splenectomy, postsurgery, and as a result of inflammation. Secondary thrombocytosis does not constitute a significant thrombotic risk.

Transfusion Medicine in Critical Care

Aryeh Shander, MD; Carmine Gianatiempo, MD and Lawrence T. Goodnough, MD

KEY POINTS

- 1 Patient blood management (PBM) is the timely application of evidence-based medical and surgical concepts designed to maintain hemoglobin (Hb) concentration, optimize hemostasis, and minimize blood loss in an effort to improve patient outcome.
- 2 Anemia in the critically ill patients is often multifactorial and can be traced to one or a combination of iron deficiency, inflammatory responses, blunt response to endogenous erythropoietin, bleeding and aggressive diagnostic blood draws that are common in many intensive care units (ICUs).
- 3 The use of hemoglobin as the only “trigger” for red blood cell (RBC) transfusion should be avoided, and transfusion decisions should be made based on other parameters such as patient’s volume status, evidence of shock, duration, and severity of anemia, and cardiopulmonary status of the patient.
- 4 The benefit of fresh frozen plasma (FFP) administration remains controversial and with the advent of more specific factor concentrates, its indications are on the decline.
- 5 Higher plasma (and platelet) to RBC ratios as part of “balanced” transfusion protocols during early resuscitation of trauma patients may be associated with better survival, but is still under investigation.

INTRODUCTION TO PATIENT BLOOD MANAGEMENT

Blood transfusion occurs in 1 of every 10 hospital admissions that includes an invasive procedure, and has been identified as one of the top 5 most frequently overused therapeutic procedures in the United States.^{1,2} Allogeneic blood transfusions have been associated with unfavorable patient outcomes, including morbidity and mortality³; and a significant percentage of transfusions to hospitalized patients have been identified to be inappropriate.⁴ These observations have led to proposals that exposure

to blood transfusion should be regarded as quality indicators for clinical services.

Awareness of the risks, costs, and trends of blood inventory has stimulated interest in examining clinical implications of transfusions. Established in 2000, the Society for the Advancement of Blood Management (SABM, www.sabm.org) recognized the unmet need and developed the concept of PBM that changed the focus from transfusion of products (blood) to the patients’ needs with the emphasis on improving patients’ outcome. PBM is defined by SABM as “the timely application of evidence-based medical and surgical concepts designed to maintain

hemoglobin concentration, optimize hemostasis, and minimize blood loss in an effort to improve patient outcome.”ⁱ The concept has been adopted by organizations globally, ranging from the National Blood Transfusion Committee in the United Kingdom, AABB in the United States, and National Blood Authority in Australia, to the World Health Organization (WHO) as put forward in Declaration 63.12 by the 63rd World Health Assembly.^{5,6}

The PBM strategies in general have included management of anemia, minimization of blood loss, and increased focus on evidence-based transfusion practices, 3 strategies which form the pillars of PBM.⁷ It should be noted that despite many similarities, the “product-centered” concept of blood management—the predecessor to PBM—primarily addresses improving blood utilization which results in improved patient safety and reduced costs with reduced exposure to RBC transfusions and their inherent risks.⁶ PBM took this concept to a higher level by giving priority to improving the patient outcomes.

Blood management has been cited as 1 of the 10 key advances in transfusion medicine over the last 50 years,⁸ and it is being increasingly adopted as a standard of care across the globe.⁵ We have reported successful implementation of a system of clinical decision support (CDS) using a best practice alert (BPA) at computerized provider order entry (CPOE)⁹ in order to improve blood utilization at our institution. As already indicated, this is just one aspect of numerous strategies that are utilized as part of a PBM program, and below we address some other PBM strategies.

Anemia Prevention, Screening, and Management

Anemia is a major risk factor for transfusion and an independent predictor of increased morbidity and mortality and diminished quality of life in many patient populations including the critically ill.¹⁰ Anemia is particularly prevalent in critically ill patients, with a tendency to exacerbate during ICU stay.¹¹ The reported prevalence of anemia in the ICU is

understandably variable, and it usually ranges from 50% to almost 100%.¹¹⁻¹³ Anemia in the critically ill patients is often multifactorial and can be traced to one or a combination of iron deficiency, inflammatory responses, blunt response to endogenous erythropoietin, bleeding, and aggressive diagnostic blood draws that are common in many ICUs.^{14,15}

Anemia should not be left unmanaged and proper screening for and management of anemia is a key strategy in patient blood management. This is particularly important during the perioperative period. Guidelines developed under the auspices of the Network for Advancement of Transfusion Alternatives (NATA) recommend routine screening for anemia in patients scheduled for elective surgery as early as 4 weeks prior to the scheduled surgery.¹⁶ This approach will allow time for proper diagnostic workup of the anemia and its treatment, and the treating clinicians can consider rescheduling of the elective surgery if needed.⁶ While these guidelines primarily target patients undergoing elective surgeries, they can also be useful in the critical care setting, particularly for proper diagnosis and management of anemia in the critically ill patients.

Understanding the etiology of anemia is necessary to guide the treatment, although more than one etiology often coexist. The NATA guidelines propose an algorithm for detection and management of preoperative anemia with primary emphasis on assessment of iron status (serum ferritin and transferrin saturation).⁶ Iron deficiency syndromes (a spectrum including absolute iron deficiency, functional iron deficiency, and iron sequestration) are commonly present in patients. Iron deficiency can be effectively treated with iron, with several intravenous iron preparations available.¹⁷ Erythropoiesis-stimulating agents (ESAs) are another group of medications that can be used to rapidly increase red blood cell mass and hemoglobin level. These are highly useful and potent agents that should be used appropriately to balance their benefits against their documented side effects, such as increased risk of thromboembolic events.¹⁸

Reduction and Avoidance of Blood Loss

Blood loss is another important predictor and risk factor for blood transfusion is the amount of surgical

ⁱ What is patient blood management? PROFESSIONAL DEFINITION. Society for the Advancement of Blood Management. <http://www.sabm.org>. Accessed August 2, 2014.

blood loss.¹⁹ This issue is most commonly encountered in surgical patients (including critically ill surgical patients), but it can also affect all other critically ill patients. Efforts should be made to avoid any unnecessary blood loss, and to retrieve and salvage the shed blood if blood loss occurs (red cell salvage). Several studies have supported the safety and efficacy of red cell salvage in intra- and postoperative periods.²⁰ Hemostatic agents, tools such as electrocautery, and approaches such as minimally invasive procedures are other important strategies for reducing surgical blood loss.²¹ Of particular interest is the use of lysine analogues including tranexamic acid in reducing blood loss and improving patient outcomes in various settings including surgical and critically ill trauma patients.^{22,23}

Close surveillance and monitoring of patients in the postoperative period for signs of bleeding and immediate attention to control it is very important. Last but not least, special consideration should be given to diagnostic blood draws which can be a significant source of blood loss, with reports indicating an average of 40 mL per day of blood draws in the ICUs.²⁴ Measures to control and reduce this source of blood loss in the critically ill patients include elimination of unnecessary and standing orders and limiting the volume of the blood draws to the minimum needed to achieve the results.²⁴

Evidence-Based Transfusion Practices

Another important aspect of PBM is the justified utilization of allogeneic blood components to achieve clear clinical end points. Several physiologic mechanisms are in place to maintain the oxygen delivery to the tissues despite reduced blood oxygen-carrying capacity in anemia. These include improved ventilation-perfusion matching in the lungs, increased heart function and cardiac output, redistribution of vascular flow toward more critical tissues, and increased extraction of oxygen from blood at tissue site. Thanks to these and other physiologic adaptations, oxygen consumption at the tissues remains relatively unchanged despite substantial changes in oxygen-carrying capacity of blood due to anemia. With progress of anemia, however, a point is reached that these compensatory mechanisms are no further sufficient, and tissue oxygen consumption drops as

hypoxia develops.¹⁰ In such situations, transfusion of red blood cells alongside other management strategies to increase oxygen delivery (eg, supplemental oxygen therapy) or decreased oxygen need (eg, neuromuscular block or control of heart rate) is critical in avoiding ischemia.^{7,10}

The issue is further complicated in the critically ill patients, as many of these compensatory mechanisms can already be disrupted (eg, respiratory or cardiac failure). Critical illness is often associated with increased oxygen demand and consumption at tissues, further compromising the tolerance of anemia and increasing the likelihood of the patients becoming hypoxic.²⁴ Judicious use of allogeneic blood products when the potential benefits outweigh the risks remains an important aspect of PBM, and evidence-based guidelines for use of these treatments in the critically ill patients are discussed in subsequent sections.

UTILIZATION OF BLOOD COMPONENTS IN ICU

Anemia—preexisting or new onset—is common in the critical care units (ICUs), and blood transfusions are routinely employed to “correct” anemia in this setting. In a surgical ICU, about 19% of the patients had Hb less than 7 g/dL and 30% had Hb levels between 7 and 9 g/dL,¹² indicating that a significant number of ICU patients were anemic (many, moderately or severely anemic) according to the WHO definition of anemia.¹⁰ The reported incidence and prevalence were 46.6% and 68%, respectively among cancer patients admitted to another ICU.¹³ Another prospective study reported that almost all consecutive patients admitted to a general ICU were anemic, and patients’ Hb level continued to drop during their ICU stay.¹¹ The etiology of anemia in the ICU is varied and often multifactorial, and can include iron deficiency, inflammatory responses, blunt response to endogenous erythropoietin, bleeding and aggressive diagnostic blood draws.^{14,15} A large and evergrowing body of evidence supports the independent link between anemia and unfavorable clinical outcomes in various patient populations including the critically ill.¹⁰

Although transfusion of blood components in ICU is common, the clinical evidence to guide the use of these products is limited. It has been

estimated that greater than 40% of patients receive one or more RBC transfusions while in the ICU, and about 90% of transfusions are provided in the context of stable anemia without evidence of need or benefit of the transfused blood.²⁵ In a matched-cohort study of nonbleeding critically ill patients with moderate anemia (Hb between 7 and 9.5 g/dL), RBC transfusions were associated with increased mortality and nosocomial infections.²⁶ Several other studies have indicated that transfusions are associated with worsening of clinical outcomes, and they are often ineffective in improving oxygen consumption, questioning the main reason they are given to the patients in the first place.^{10,27}

In a single-center study it was reported that about 50% of patients received blood products during their ICU stay: 48.3% received packed red blood cells; 18.3% received FFP, and 8.4% of patients received platelet transfusion. Interestingly, approximately one-fourth to one-half of these transfusions were not medically indicated.²⁸ According to a study performed in 29 ICUs in the United Kingdom, 9% of the patients received platelet transfusion in ICU, one-third of which occurred in patients with platelet counts above $50 \times 10^9/L$ and in absence of clinically significant bleeding.²⁹ In a prospective cohort study of septic shock patients, 57% of the patients received FFP transfusion during ICU stay; one-third of the plasma transfusions were given without any evidence of bleeding or any planned invasive procedures.³⁰ A survey has also shown substantial variations in transfusion practices and uncertainties toward indications of plasma transfusions in ICU among clinicians.³¹

On the other hand, one study in 47 ICUs in Australia and New Zealand indicated (although somewhat broadly interpreted) that 98% of RBC transfusions were performed according to the national transfusion guidelines, while only 47% of platelet, 71% of FFP, and 12% of cryoprecipitate transfusions were done according to the guidelines.³² Of note, in this study 40.2% of the RBC transfusions were given to improve oxygen delivery (DO_2) and 43.6% of the RBC transfusions were given for bleeding (nearly half of which were considered to be “minor”).³² As will be discussed later, these numbers may not be necessarily consistent with current evidence or guidelines for use of RBC transfusions in critically ill patients.

Somewhat similar results were observed in a single-center study in Spain where RBC transfusion seem to be more restrictive than any of the other blood components.³³ These findings are also consistent with the high frequency of blood product transfusion and high variability in transfusion practices reported in many other studies and reviews.³⁴

Evidence-based general recommendations for transfusion of RBCs, plasma, and platelets were discussed in previous sections. Here we take a closer look at these blood components and their usage in ICU.

Red Blood Cells

RBC is a heterogeneous group of products that includes packed red blood cells (PRBCs), gamma-irradiated blood, washed RBCs, and whole blood. PRBC is the preparation used in most clinical situations. One unit PRBC has an average volume of 300 mL, of which two-thirds is consisted of RBCs, and the remaining is mostly the preservative solution. Each unit has a hematocrit of approximately 55% to 60% and approximately 200 mg of iron.³⁵ PRBCs undergo leukoreduction (removal of leukocytes) and hence are known as leukoreduced PRBCs. Universal leukoreduction of allogeneic blood as part of blood banking process has been implemented in an increasing number of nations. Leukoreduction has been suggested to improve the safety profile of allogeneic blood by reducing the risk of febrile transfusion reactions, alloimmunization and transmission of some pathogens (cytomegalovirus [CMV] and possibly prions), but the overall impact on patient outcomes and its cost-benefits are still a matter of debate.³⁶ Although leukoreduced PRBC units are gaining universal acceptance, these units are more costly, and in some instances may be preferred for chronically transfused patients, potential transplant recipients, patients with previous transfusion reactions, patients undergoing cardiopulmonary bypass, and CMV seronegative patients at risk for CMV infection.

Gamma-irradiated RBC units are produced by subjecting the units of blood to external-beam radiation. This process results in destruction of donor T-lymphocytes in the blood and is effective for prevention of graft-versus-host disease (GVHD) in the transfused patients, particularly the

transplant patients and severely immunocompromised patients. However, irradiation is associated with several changes in the RBCs which could result in reduced life span of these units.³⁷

As the name suggests, washed RBCs are produced by “washing” the donor cells with normal saline solution to remove as much of the proteins and macromolecules of the donor plasma as possible. These units are preferred for patients with immunoglobulin A deficiency and those at high risk for anaphylactic reaction.³⁸ Lastly, whole blood is rarely indicated and seldom available and it is most often considered in the context of massive blood transfusion. The rationale is to avoid dilutional deficiencies that can be caused with transfusion of other components.³⁹

For many decades, transfusion of RBCs was used to maintain a blood hemoglobin level above 10 g/dL or a hematocrit above 30% (the 10/30 rule), even though these thresholds were arbitrary numbers with no proven physiologic or clinical significance. Emergence of a large body of work and clinical evidence, especially within the last 25 years, has changed transfusion practice to balance the benefit of treating anemia with the desire to avoid unnecessary transfusion and its associated risks and complications in various medical settings including in the ICU.⁴⁰ However, there is evidence to suggest that considerable variation in RBC transfusion practices in critical care still exists. A Canadian scenario-based national survey sent to critical care practitioners demonstrated that transfusion thresholds differed significantly ($P < 0.0001$) when faced with different medical scenarios.⁴¹ A study by Herbert and colleagues examined blood use in 5298 consecutive patients admitted to 6 tertiary level ICUs.⁴² The overall number of transfusions per patient day ranged from 0.82 ± 1.69 to 1.08 ± 1.27 between institutions ($P < 0.001$).

The multicenter Transfusion Requirements in Critical Care (TRICC) trial showed that a restrictive strategy, that is, a threshold for transfusion for hemoglobin less than 7 g/dL in critically ill patients is safe.⁴³ Furthermore, there is a trend toward decreased hospital morbidity and mortality when compared to patients with a more liberal (transfusion for a hemoglobin < 10 g/dL) transfusion strategy. An exception to this strategy is patients with

acute myocardial ischemia. The optimal transfusion threshold for these patients has not been determined because such patients were excluded from most clinical trials. Similarly, the Transfusion Requirements in Pediatric ICU (TRIPICU) study showed that in stable, critically ill children, using a Hb threshold of 7 g/dL for transfusion can reduce the transfusions compared with a Hb threshold of 9.5 g/dL without negatively affecting the outcomes.⁴⁴ Subsequent subgroup analyses of this trial further supported the restrictive transfusion strategy in patients with higher severity of illness, postsurgical patients and those with respiratory dysfunction, sepsis, neurologic disorders, and severe trauma.⁴⁵

The joint taskforce of Eastern Association for Surgery of Trauma (EAST) and the American College of Critical Care Medicine (ACCM) of the Society of Critical Care Medicine (SCCM) have developed clinical practice guidelines for RBC transfusion in the critically ill patients.³⁶ Based on these guidelines, RBC transfusion is indicated for patients with evidence of hemorrhagic shock, and it may also be indicated for those with evidence of acute hemorrhage and hemodynamic instability or inadequate DO_2 . According to these guidelines, in hemodynamically stable critically ill patients, transfusion of RBC at hemoglobin level of less than 7 g/dL is as effective as using a more liberal trigger of Hb less than 10 g/dL, with the possible exception of patients with acute myocardial infarction or unstable myocardial ischemia, given the paucity of data on these patients. However, the guidelines emphasize that use of hemoglobin as the only “trigger” for RBC transfusion should be avoided, and transfusion decisions should be made based on other parameters such as patient’s volume status, evidence of shock, duration and severity of anemia, and cardiopulmonary status of the patient.³⁶ Based on these guidelines, RBC transfusion should be **considered** in critically ill patients with Hb less than 7 g/dL in following conditions: patients who require mechanical ventilation (despite lack of conclusive evidence), resuscitated trauma patients, and patients with stable cardiac disease. Despite lack of supportive evidence, the guidelines recommend that RBC transfusion may be considered in critically ill patients with acute coronary syndrome with Hb less than or equal to 8 g/dL. The guidelines recommend against RBC

transfusion as an absolute method to improve tissue oxygen consumption (VO_2). When indicated and with exception of acute hemorrhage, RBC transfusion should be given 1 unit at a time, with reevaluation of the patient prior to giving the next unit.³⁶ The guidelines call for individual assessment of transfusion needs in each septic patient given that optimal transfusion threshold and the impact of transfusion on oxygen consumption in these patients are not well established.³⁶

In critically ill patients with or at risk of acute respiratory distress or lung injury, the guidelines call for making all efforts to avoid RBC transfusions after completion of resuscitation, and to appropriately diagnose transfusion-related acute lung injury (TRALI) given its prominence as a leading cause of morbidity and mortality in transfused patients. The guidelines proscribe against use of RBC transfusion with the goal of facilitating weaning patients from mechanical ventilation.³⁶

The guidelines indicate no benefit for liberal transfusion (at $\text{Hb} > 10 \text{ g/dL}$) in patients with moderate-to-severe traumatic brain injury (TBI). In patients with subarachnoid hemorrhage (SAH), transfusion decisions must be made on case-by-case basis since the optimal transfusion threshold and the impact of transfusion on outcomes in these patients are undetermined.³⁶ The guidelines provide an overview of various blood management strategies that can be used in critically ill patients to reduce the avoidable allogeneic transfusions and improve the outcomes of the patients.³⁶ Of note, the guidelines emphasize the insufficiency of the available evidence in many of the discussed topics,³⁶ underscoring the importance of further research in the field.

Similar to general critically ill patient populations, evidence regarding transfusion in critically ill children is very limited. Anemia and transfusion are both common in these patients, and in addition to proper management of anemia, transfusion decisions should be made based on the individual patient's factors and characteristics, rather than using general transfusion triggers, and appropriate blood management strategies should be utilized.⁴⁶

Another set of transfusion guidelines for the critically ill adult patients has recently been developed by the British Committee for Standards in Haematology (BCSH).²⁴ These guidelines share many

similarities with the ACCM/SCCM transfusion guidelines discussed above.³⁶ They recommend a Hb level of less than or equal to 7 g/dL (with a target Hb range of $7\text{--}9 \text{ g/dL}$) as the default transfusion threshold in critically ill patients in general. Again, despite lack of evidence, a target Hb level of 7 to 9 g/dL has been recommended in patients with TBI as well as during later stages of severe sepsis (vs a Hb target of $9\text{--}10 \text{ g/dL}$ during early resuscitation of severe sepsis with evidence of inadequate DO_2). Similarly, despite lack of supporting data, the guidelines recommend that Hb level of patients with stable angina should be maintained above 7 g/dL . In addition, a target Hb level of 8 to 10 g/dL is recommended in patients with SAH and the Hb should be kept greater than 8 to 9 g/dL in patients with acute coronary syndrome. Finally, a target Hb level of greater than 9 g/dL is recommended in TBI patients with evidence of cerebral ischemia and patients with acute ischemic stroke.²⁴ Similar to the ACCM/SCCM guidelines, the BCSH guidelines recommend against use of RBC transfusion to facilitate weaning patients from mechanical ventilation if Hb greater than 7 g/dL .²⁴

Most recently and as part of its evidence-based “Choosing Wisely” recommendations, the Critical Care Societies Collaborative (CCSC)—a multidisciplinary group composed of the American Association of Critical-Care Nurses (AACN), American College of Chest Physicians (ACCP), American Thoracic Society (ATS), and SCCM—have identified transfusion of RBCs as one of routine practices in the ICUs that should be questioned, given its doubtful benefits and certain harms. The group has made the recommendation to not transfuse RBCs in hemodynamically stable, nonbleeding critically ill patients with Hb greater than 7 mg/dL .ⁱⁱ The AACN—as part of the CCSC—has identified 5 routine critical care practices that should be questioned because they may not always be necessary and could, in fact, be harmful.

Plasma Products

Plasma is the portion of whole blood that remains after white cells, red cells, and platelets are removed

ⁱⁱ Critical Care Societies Collaborative (CCSC)—Critical Care. Five things physicians and patients should question. <http://www.choosingwisely.org/doctor-patient-lists/critical-care-societies-collaborative-critical-care/>. Accessed February 20, 2014.

by centrifugation. Plasma contains various macromolecules namely procoagulation and anticoagulation factors, albumin, and immunoglobulins. It is indicated when inadequate hemostasis is present and the benefits of correction outweighs risks of transfusion. However, the benefit of plasma administration remains controversial, and with the advent of more specific factor concentrates, its indications are on the decline.

Plasma products come in a number of forms. FFP is separated from freshly drawn blood by removing the cellular components. It is frozen for storage and thawed when needed for transfusion. Once thawed, FFP needs to be transfused within 24 hours as factors V and VIII decline with time. Also, FFP must be cross-matched to confirm ABO compatibility. Thawed plasma is a plasma not transfused within 24 hours of thawing. It can be transfused for up to 5 days if it is kept refrigerated at 1°C to 6°C. Other plasma products include jumbo apheresis plasma, single-donor, liquid plasma, and solvent/detergent-treated (SD) plasma (Octaplas). Cryoprecipitate is a by-product of FFP and it is obtained by thawing FFP at 4°C and collecting the white precipitate. It is rich in von Willebrand factor (vWF), factors VIII and XIII, and fibrinogen. It allows replacement of these factors using much smaller volumes compared with plasma volumes needed to achieve the same level of factors.

A prospective, observational study of an adult ICU determined that the incidence of laboratory evidence of coagulopathy was 67% of patients and 14% of patients received transfusion of FFP.⁴⁷ Approximately one-third of FFP usage is for correction of elevated international normalized ratio (INR) prior to invasive and surgical procedures⁴⁸; however, there is a paucity of evidence to support this practice. Furthermore, plasma should not be used to reverse supratherapeutic warfarin effects, unless in the presence of active bleeding or need for invasive or surgical procedures because plasma products are only partially effective,⁴⁹ its action is of short duration and it could increase the risk of hypervolemia (transfusion-associated circulatory overload [TACO]) and other complications such as TRALI.⁵⁰

The response to plasma transfusion is directly proportional to the difference between the patient level of coagulation factors and that of the infused

plasma. Thus, patients with severe deficiencies are more likely to see a more significant change in their INR than patients with mild deficiencies. It is worth noting that the INR of a unit of plasma is usually elevated itself and tends to be around 1.3.⁵¹ The dose of FFP transfused to patients is also commonly erroneous and often inadequate to achieve the desired impact on coagulation. The response to cryoprecipitate transfusion is even more difficult to predict; 10 bags of cryoprecipitate is expected to increase fibrinogen level by approximately 70 mg/dL. With availability of prothrombin complex concentrates (PCC)—particularly the 4-factor products—there is less need to plasma for reversing the effects of warfarin.⁵² Use of plasma in conjunction with other blood components to create a “balanced” transfusion strategy in trauma resuscitation has been gaining more interest. The Prospective, Observational, Multicenter, Major Trauma Transfusion (PROM-MTT) study has indicated that higher plasma (and platelet) to RBC ratios during early resuscitation of trauma patients were associated with better survival in patients who received at least 3 units of RBC during the first 24 hours.⁵³ Another phase III trial in massively transfused trauma patients, Pragmatic, Randomized Optimal Platelets and Plasma Ratios (PROPPR) study compared the effectiveness of transfusing patients with severe trauma and major bleeding using plasma, platelets and red blood cells in a 1:1:1 ratio compared with a 1:1:2 ratio. No significant differences in mortality were detected at 24 hours or at 30 days. However, exsanguination, which was the prominent cause of death within the first 24 hours, was significantly decreased in the 1:1:1 group (9.2% vs 14.6% in the 1:1:2 group, $P = 0.03$) and more patients achieved hemostasis in the 1:1:1 group (86% vs 78%, $P = 0.006$).⁵⁴ Of note, rapid anatomic control of bleeding (e.g., primary surgical hemostasis) was not reported and might have influenced the hemostasis results. Furthermore, ratio-based transfusion is not intended to replace transfusion based on coagulation testing but rather to supplement it with the goal of more effective control of acute trauma coagulopathy and hemorrhagic shock.⁵⁵

Platelets

Platelet concentrates are prepared from whole blood by centrifugation at low speeds to separate

the erythrocytes. The supernatant, “platelet-rich plasma” is then centrifuged at high speeds to separate the platelets. This results in “pooled concentrates.” It is less expensive to produce, but more donors are required because the yield is lower; 6 to 10 donors are required per platelet transfusion. Single-donor apheresis platelet concentrates are obtained by apheresis; that is, whole blood from a donor passes through a device that separates the platelets while returning the remainder to the donor. This process is more expensive, but it has a higher yield, fewer donors are necessary (one donor per platelets transfusion), and hence the risk of transmission of infection is lower compared with pooled platelets. Platelet concentrates can be stored for up to 7 days, but platelets start losing their efficacy (viability) after 3 days.⁵⁶

The generally expected response to transfusion of 1 unit of platelets is a rise in platelet count by 5 to 10,000; presence of platelet destruction or consumption at the bleeding site can blunt this response. Efficacy is reduced by the presence of antibodies to ABO antigens on platelets or to leukocyte antigens. This can be ameliorated with transfusions of ABO-compatible platelets or using single-donor concentrates.

Current indications for platelet transfusions in thrombocytopenic patients can be therapeutic or prophylactic.⁵⁶ These include the following:

- Platelet count less than 10,000, to reduce the risk of spontaneous bleeding
- Platelet count less than 50,000, in patients who are actively bleeding, or are scheduled for invasive procedures, or have a qualitative platelet defect
- Platelet count between 70,000 and 100,000, with a central nervous system (CNS) injury, or undergoing neurosurgery or intrathecal catheter insertion
- Normal platelet count, with active bleeding due to platelet dysfunction (although platelet transfusion is not consistently effective in these patients)

As discussed earlier, the most efficient use of platelets (alongside plasma) as part of “balanced” transfusion protocols to supplement RBCs during trauma resuscitation is still under investigation.

Complications

A number of complications can result from transfusions of blood products. Often, the greater the volume of transfusion, the greater is the risk or severity of the complication. These complications can be infectious (human immunodeficiency virus [HIV], hepatitis B virus [HBV], hepatitis C virus [HCV], hepatitis A virus [HAV], human T-cell leukemia/lymphoma virus [HTLV], parvovirus B19, bacterial) or noninfectious which include acute hemolytic reactions, delayed hemolytic reactions, febrile reactions, allergic reactions, posttransfusion purpura (rare), acute lung injury (TRALI), immunomodulation, that is, the immunosuppressive activity of allogeneic blood transfusion, and transfusion-related GVHD.⁵⁷ Other complications include volume overload (TACO) with consequent pulmonary edema due to expansion of the intravascular volume especially in patients with compromised cardiac or renal function or due to fluids shift due to increased oncotic pressure particularly with FFP; hypothermia if large volumes are transfused rapidly (blood products are stored at cold temperatures); coagulopathy presumably as a result of hemodilution from resuscitative fluids and acidosis secondary to tissue hypoxia; and life-threatening hyperkalemia (especially in pediatric population with relatively large transfusion volume). Citrate is present in stored blood products and can lead to metabolic alkalosis and hypocalcemia.⁵⁷

With significant advances in the screening and testing of donors for transmittable diseases, the infectious risks are very rare with an incidence ranging from 1 for every 7,800,000 units of RBC units transfused for HIV to 1 in 50,000 units transfused for bacterial contamination. However, the incidence of bacterial contamination is much more common with platelet transfusion with a reported incidence of 1 infection per 1000 units of platelets transfused,⁵⁷ and septic transfusion reactions remain a concern with platelet transfusions, making the case for additional testing. The American Association of Blood Banks (now referred to as AABB) standards call for the use of enhanced bacteria detection methods and require blood banks or transfusion services to employ methods to detect bacteria in all platelet

components.ⁱⁱⁱ The nature of allogeneic blood and reliance on donors and screening tests means that the risk of transmitting infections through blood can never be fully eliminated and some residual risk of undetected and/or emerging pathogens remains.⁵⁷

Acute hemolytic reactions occur due to antibodies, usually IgM in the recipient's serum against major antigens present on the donor's RBCs. These are almost always due to ABO incompatibility. The frequency has been described to range from 1 in 40,000 to 1 in a 1,000,000. These occur within the first several minutes of transfusion and manifest acutely with fever, tachycardia, hypotension, dyspnea, and back and chest pain.⁵⁷

Delayed hemolytic reactions usually occur more than 24 to 48 hours, and up to 7 to 10 days after the transfusion. They result from antibodies in the recipient's serum directed toward minor antigens on the donor's RBCs. These reactions occur with a frequency of 1 in 7000 with a sudden decrease in hemoglobin. They are often mild and frequently undetected and require no specific therapy.⁵⁷

Febrile nonhemolytic reactions result from the presence of antileukocyte antibodies induced by previous transfusions acting against leukocytes in the donor's product or secondary to accumulated cytokines in stored blood components. It is relatively frequent, ranging from 1 in 20 (with platelets transfusion) to 1 in 300. These reactions are manifested acutely by an increase in body temperature. These are usually self-limited, but can be treated with antipyretics and the transfusion allowed to be completed. Leukoreduction of stored blood can reduce the incidence of febrile nonhemolytic reactions.⁵⁷

Allergic reactions occur because of presence of allergens in the donor's blood component to which the patient has preexisting antibodies; they do not require previous blood exposure. These reactions can vary from urticaria and/or bronchospasm with a frequency of 1 in 100 to anaphylaxis, with a frequency of 1 in 40,000. Patients with IgA deficiency are especially at risk for severe anaphylactic reactions. These reactions are best prevented with washed RBCs, but

can be treated with high-dose corticosteroids, antihistamines, and airway protection.⁵⁷

TRALI is related to presence of alloreactive plasma antibodies within red blood cell products or FFP which can lead to agglutination and diffuse activation of leukocytes with subsequent diffuse capillary damage of the pulmonary vasculature and rapid onset of acute pulmonary injury and development of inflammatory pulmonary edema. The pulmonary dysfunction may not manifest for hours to, less frequently, days after the transfusion was administered. The incidence of TRALI varies from 1 in 700, especially with FFP to 1 in 5000; however, this incidence may be underestimated as the reaction may go unrecognized.⁵⁷

The adverse events discussed here are often recognized as known immediate complications of allogeneic blood transfusion, and most of the time, a causal link can be established and recognized. In critically ill patients, it is difficult at times to recognize these events because of the underlying acuity of the illness. Hypotension, sepsis, and shock can accompany some of the complications stated earlier or can occur independent of transfusion and due to the underlying disease. What complicates this picture is the delayed adverse outcomes that are associated with allogeneic transfusions. Several studies have shown that blood transfusions are independently associated with increased risk of wound infection, pneumonia, sepsis, and other nosocomial infections, multiorgan failure, systemic inflammatory response syndrome (SIRS), and other morbidities and mortality.^{10,36}

CONCLUSIONS

Anemia and transfusion are common in critically ill patients and both are independently associated with worsening of patient outcome. Substantial variations in transfusion practices have been documented. Evidence-based guidelines for transfusion of blood components have been developed and available, even though the underlying "evidence" is often limited. Additionally, several PBM strategies are available to reduce and avoid unnecessary transfusions and improve the outcomes of critically ill patients. Use of these strategies alongside adherence to evidence-based transfusion guidelines are effective measures that can reduce inappropriate transfusions,^{32,33} and improve the patients' outcomes.

Anticoagulation

Victor F. Tapson, MD and Shant Shirvanian, MD

KEY POINTS

- 1 Anticoagulation is the key in the management of venous thromboembolism (VTE), atrial fibrillation (AF), mechanical heart valves, and idiopathic pulmonary arterial hypertension (IPAH).
- 2 Critically ill patients are at increased risk for complications with anticoagulant therapy due to their underlying disease states, presence of thrombocytopenia, coagulopathy, renal and hepatic failure, need for invasive procedures, and the potential for major surgery.
- 3 Intravenous unfractionated heparin (UFH) remains the most commonly utilized parenteral therapy when therapeutic doses are needed in the critically ill. Monitoring with the activated partial thromboplastin time (aPTT) or heparin level (anti-factor Xa assay) is required.
- 4 Heparin resistance may occur due to nonspecific binding of the drug to various plasma proteins, altered intravascular volume, and/or increased heparin clearance. In cases of heparin resistance, anti-Xa level should be utilized for monitoring.
- 5 Low-molecular-weight heparins (LMWHs) have several advantages over UFH including greater bioavailability and more predictable effects, lesser incidence of thrombocytopenia, and in general do not require monitoring except in patients who are morbidly obese, pregnant, or with severe renal insufficiency.
- 6 Argatroban is a synthetic direct thrombin inhibitor that is approved for prevention and treatment of VTE in patients with heparin-induced thrombocytopenia (HIT).
- 7 Novel oral anticoagulants inhibit either thrombin (factor IIa) or factor Xa. They include rivaroxaban, apixaban, edoxaban and dabigatran etexilate. These agents do not require routine monitoring.
- 8 The risk/benefit of anticoagulant discontinuation for emergent procedures including surgery depends on the reason the patient is anticoagulated, the bleeding risk imparted by the procedure, and concomitant comorbidities.
- 9 Warfarin and other vitamin K antagonists (VKAs) may be reversed with vitamin K and/or fresh frozen plasma (FFP).
- 10 Four-factor prothrombin complex concentrate (PCC) is approved for use in the United States for warfarin reversal in the setting of severe bleeding.

INTRODUCTION

Anticoagulation is the mainstay of therapy for VTE and is a key therapeutic component for a number of other clinical settings including atrial fibrillation (AF), mechanical heart valves, and idiopathic pulmonary arterial hypertension (IPAH). In the critical care setting, the use of anticoagulation is frequently warranted, but is often associated with an increased risk for complications based on underlying disease states, necessary invasive procedures, trauma, thrombocytopenia, coagulopathy, renal failure and hepatic failure, and the potential for major surgery. Reversing anticoagulation must be considered in certain clinical scenarios. The focus of this chapter will be anticoagulation in the intensive care unit (ICU), with a particular focus on therapeutic anticoagulation.

Anticoagulation in the critically ill patient requires therapeutic levels when treating an acute condition such as acute VTE. Given the high risk of morbidity and mortality caused by VTE, patients in the ICU, almost without exception, require VTE prophylaxis. Mechanical prophylaxis is used when pharmacologic prophylaxis is contraindicated or in certain lower-risk settings.

The ideal anticoagulant would be effective, easily administered with a predictable anticoagulant effect (oral, if the patient is capable) and rapid in onset, require no monitoring, and be easily reversible. Ideally, it would cause no significant adverse effects, including thrombocytopenia, and would not cause bleeding. The latter is a virtual impossibility, based on the clinical effect required. The direct oral anticoagulants (DOACs) are a significant advance, reminiscent of how LMWH dramatically changed the anticoagulation world nearly 2 decades ago.

PARENTERAL ANTICOAGULATION

Standard, Unfractionated Heparin

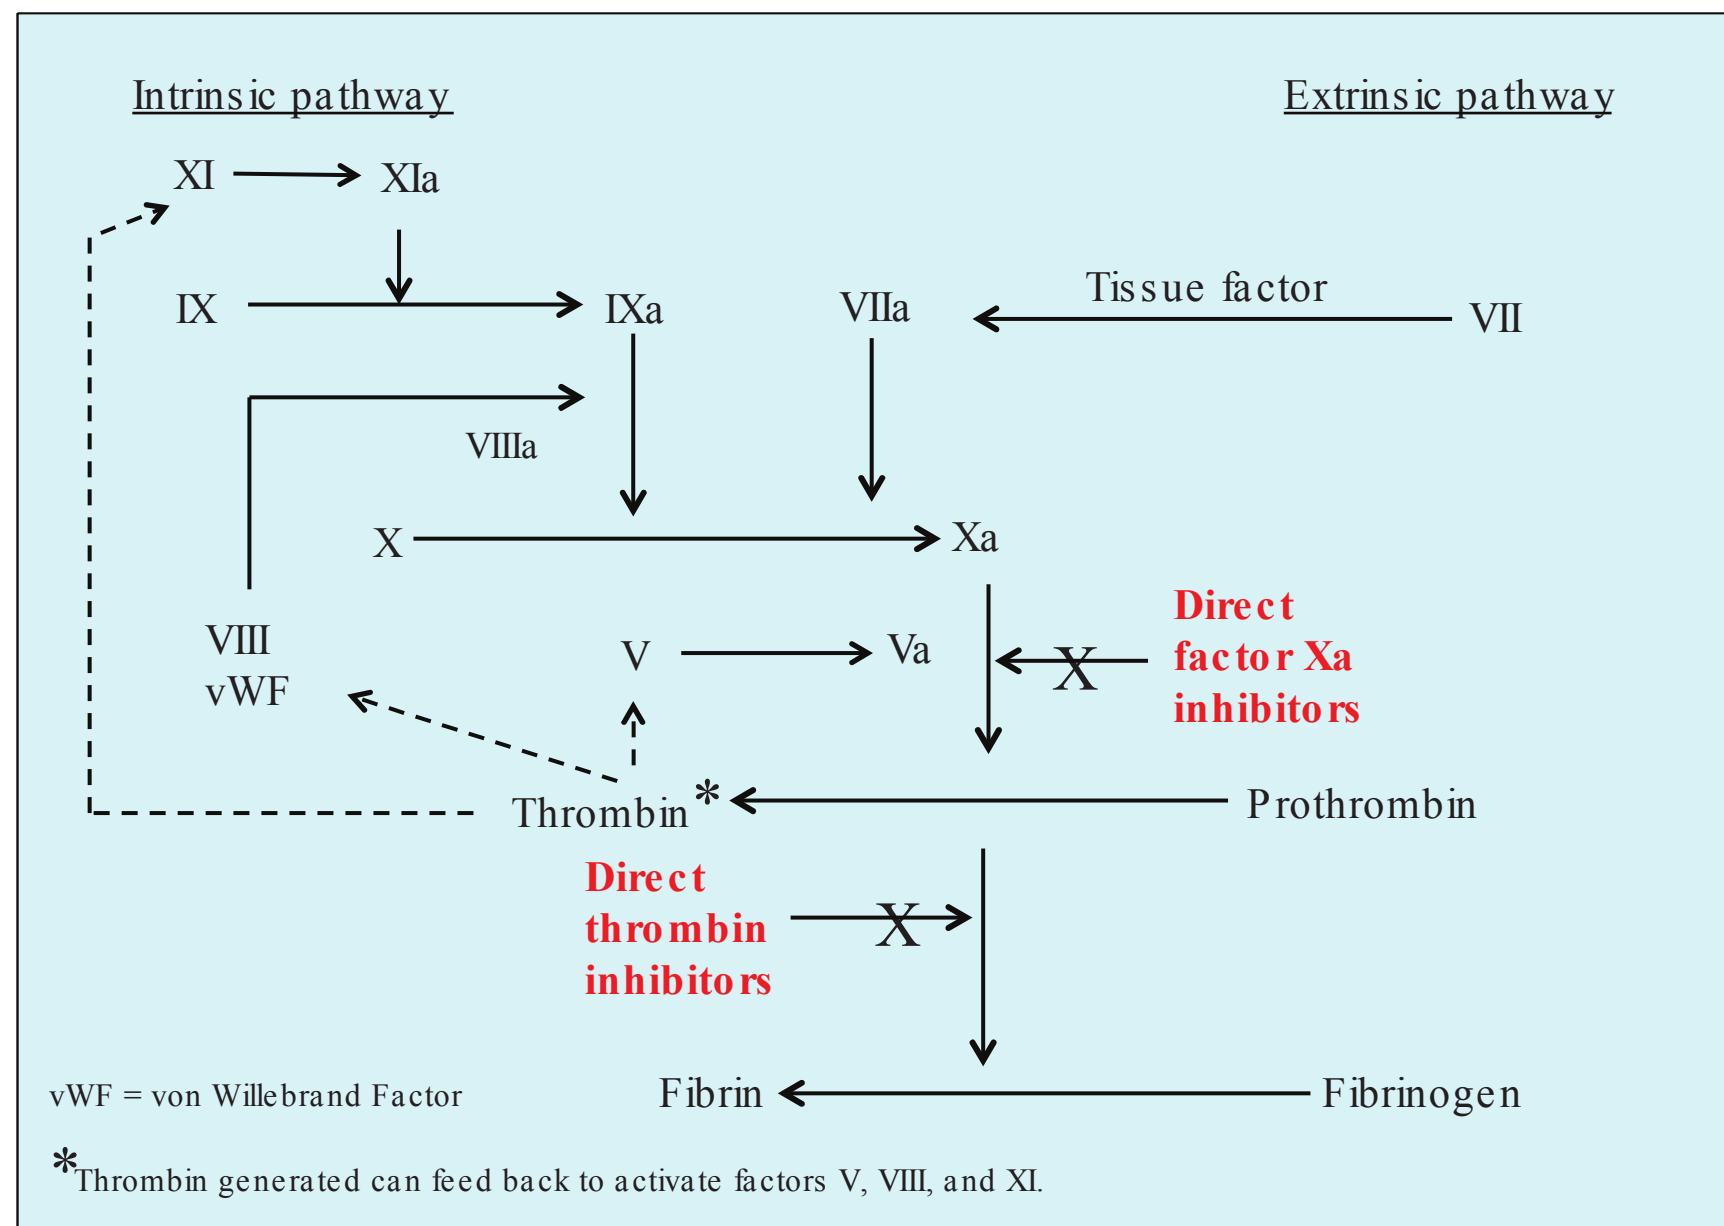

In spite of its limitations, intravenous (IV) standard UFH remains the most commonly utilized parenteral therapy when therapeutic doses of anticoagulants are required in the ICU. Monitoring with the aPTT is required. Heparin is a “promiscuous” molecule. It binds almost indiscriminately to various plasma proteins, monocytes, and endothelial cells.

Because it binds to a number of circulating proteins and cell types, different clinical conditions can significantly affect the heparin levels. The response can be thus, difficult to predict. Weight-basing heparin is crucial to hasten the achievement of therapeutic levels but monitoring is still essential ([Figure 34–1](#)). The aPTT is a clot-based, in vitro assay using citrated, platelet-depleted plasma. While the aPTT is sensitive to the inactivation of thrombin and factor Xa by UFH, it is a nonspecific assay. The therapeutic range should be a heparin concentration of 0.3 to 0.7 anti-Xa units/mL, using plasma samples from patients being treated with UFH for VTE. The aPTT range is specific for the reagent used by a given manufacturer lot. Alternatively, heparin levels (anti-factor Xa assay) can be monitored.

Decades ago, IV UFH dosing was routinely a 5000 unit bolus followed by an infusion of 1000 units/h followed by aPTT monitoring. In 1993, Raschke and colleagues¹ demonstrated that dosing heparin based on actual body weight (bolus of 80 units/kg followed by 18 units/kg/h) achieved a therapeutic aPTT at 24 hours more often than the standard dosing regimen. Furthermore, there was no difference between the 2 regimens with regard to bleeding events, although the weight-based subjects had a higher percentage of supratherapeutic aPTTs. The rate of recurrent VTE was statistically significantly higher in the non-weight-based regimen.

In this study, only 9 patients in the weight-based arm weighed more than 100 kg, and the largest patient was 131 kg making it difficult to extrapolate these findings to obese patients in general.¹ The volume of distribution of heparin is about the same as blood volume. Blood volume is increased in obesity, but adipose tissue has less blood volume compared with lean body tissue. This suggests that using actual body weight for the morbidly obese could increase the incidence of supratherapeutic aPTTs as well as the bleeding risk.

Several studies and reviews have attempted to address the dilemma of heparinization in the obese. One concluded that actual body weight in both non-obese and obese patients should be used to calculate heparin infusion rates, as long as a dosing cap of 10,000 units and infusion rate limit of 15,000 units/h was utilized.² A smaller study also found that actual body weight in both nonobese and obese patients was appropriate.³ Still another study concluded that

Novel oral anticoagulants and the coagulation cascade

FIGURE 34–1 Thrombin (factor IIa), a serine protease, activates factors V, VIII, and XI (in turn, generating more thrombin), catalyzes the conversion of fibrinogen to fibrin, and stimulates platelet aggregation. This key role in the final steps of the coagulation cascade makes it an attractive target for new direct thrombin inhibitors such as dabigatran.

Factor Xa is also a serine protease that plays a pivotal role in the coagulation process. It represents the convergence point for the extrinsic and the intrinsic coagulation pathways. It converts prothrombin to thrombin. Thus, it is a very desirable target for the direct factor Xa inhibitors rivaroxaban and apixaban.

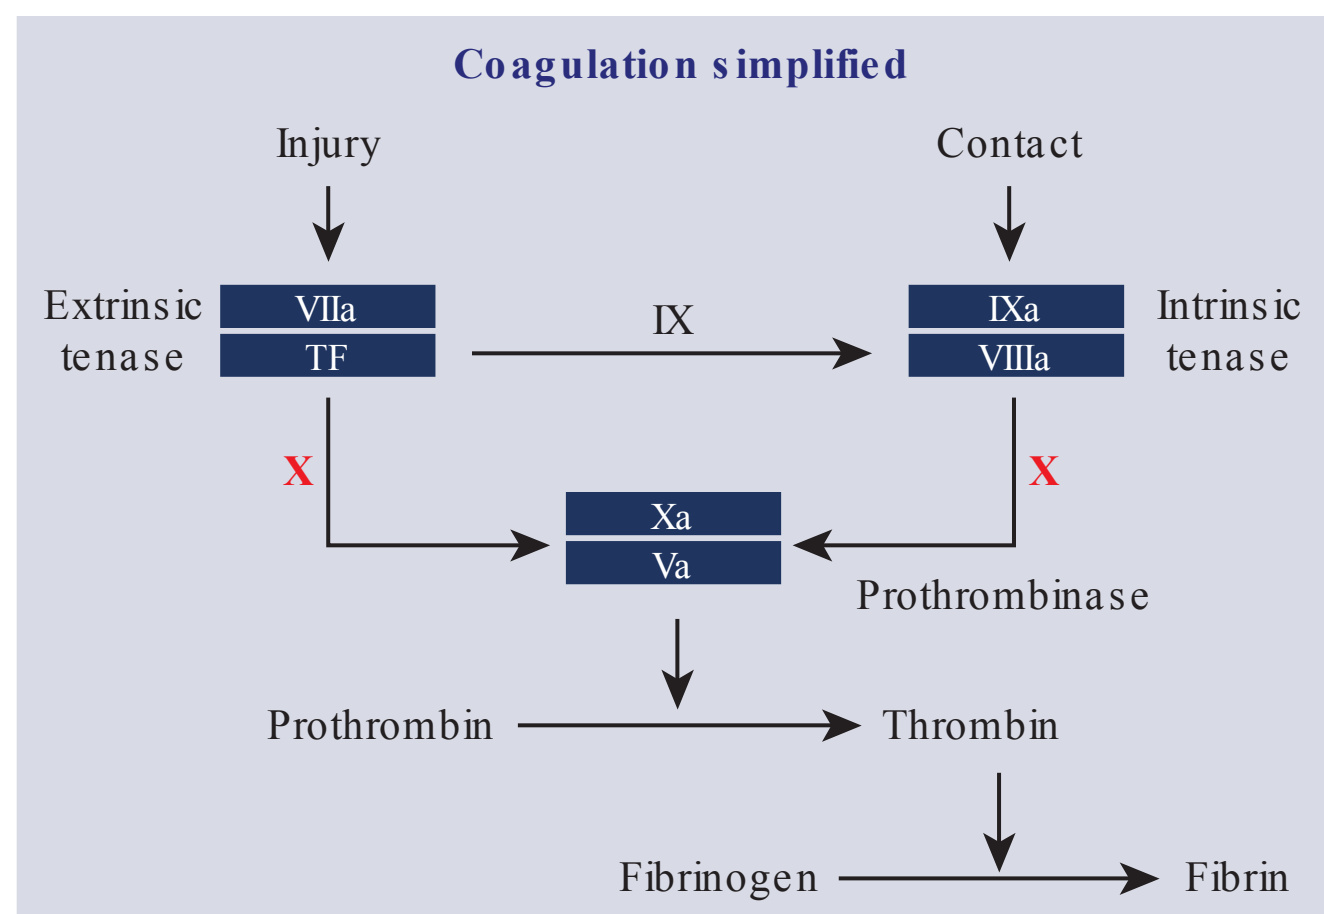

FIGURE 34–1 (Continued)

morbidly obese patients dosed according to actual body weight on a weight-based heparin nomogram were more likely to experience supratherapeutic aPTT values compared to nonmorbidly obese patients.⁴ They suggested a dosing cap but believed more data were needed. In summary, the available evidence supports the use of actual body weight for calculating heparin bolus doses and initial infusion rates for obese patients. Experience with morbidly obese patients is still limited. The concept of a dose cap remains controversial. Careful monitoring remains crucial.

Resistance to heparin may be encountered. Approximately 25% of patients with acute VTE on IV standard UFH require more than 35,000 units of heparin per day to achieve a therapeutic aPTT. Resistance may occur because of the nonspecific binding of the drug to various plasma proteins, altered intravascular volume, and/or because of increased heparin clearance.⁵ Other reasons for alterations in the aPTT dose-response include increased concentrations of clotting factors, including thrombin or factor VIII, or a reduction in anticoagulation factors such as antithrombin which may occur in the critically ill setting. In the case of apparent heparin resistance, the anti-Xa level should be utilized.⁶ This may help differentiate pharmacokinetic from biochemical heparin resistance in patients requiring high infusion rates.

Another option is to simply monitor anti-Xa levels in any ICU patient on heparin since such patients appear more susceptible to variable aPTTs.⁷ No data thus far, however, have proven better outcomes utilizing this method. In any patient found to have prolonged baseline clotting times, the heparin level by anti-Xa assay should be determined prior to initiating anticoagulant therapy.

Low-Molecular-Weight Heparins

LMWHs have distinct advantages over standard UFH as well as potential disadvantages. They are much more bioavailable than standard heparin, and are thus, more predictable. They are at least partially reversible with protamine. They appear to cause less thrombocytopenia than standard UFH. They can be given by the subcutaneous route (SC) and in most settings do not require monitoring. However, in certain populations, particularly the morbidly obese, those with renal insufficiency, and pregnant patients, these drugs may be less predictable. A creatinine clearance less than 30 mL/min requires a dose reduction or discontinuation.

While in most prophylactic and therapeutic anticoagulation settings, no monitoring of LMWH is necessary, critically ill patients who have marked metabolic derangements may be less predictable. A number of factors including hypotension, particularly requiring vasopressor therapy, renal insufficiency,

and variable absorption may affect drug efficacy. Furthermore, such conditions may rapidly change in severity, making prediction of appropriate levels more difficult.⁸ In such scenarios, when therapeutic anticoagulation is required, the goal should be a chromogenic anti-Xa assay level of 0.5 to 1.0 units/mL 4 hours after SC dosing, if the patient is on an every 12-hour dosing regimen. A higher level of 2 units/mL is recommended for a once-daily regimen.⁹ Trough or even random anti-Xa levels may also be useful when there are concerns, for example, that a LMWH may be accumulating in renal failure. The anti-Xa assay should be calibrated to the specific LMWH being utilized. Finally, while levels are generally not checked in patients on deep venous thrombosis (DVT) prophylaxis, a level of approximately 0.1 to 0.3 units/mL measured 3 to 4 hours after a SC injection would appear reasonable.¹⁰ Despite some limitations of antifactor Xa monitoring for LMWH therapy, the unreliability of SC drug administration in critically ill patients warrants the routine use of monitoring to assure adequate drug exposure.

Fondaparinux

Fondaparinux, a selective factor Xa inhibitor, has a longer half-life than the LMWHs and thus, is less useful in the ICU. For prophylaxis in total joint arthroplasty, it is prescribed as 2.5 mg SC once-daily and is as effective as LMWH. It does not appear to be associated with HIT.

Argatroban

Argatroban, a small molecule synthetic direct thrombin inhibitor (DTI) administered IV, is Food and Drug Administration (FDA) approved for prevention and treatment of thrombosis in patients with HIT. Plasma concentrations reach steady state in 1 to 3 hours. This drug is hepatically metabolized which must be considered. However, this also allows its use in renal insufficiency. Its half-life is about 50 minutes. The recommended range for the aPTT to monitor argatroban is 1.5 to 3 times control, not to exceed 100 seconds. The ecarin clotting time may have certain advantages in monitoring DTI therapy, but it is not routinely available. It has not yet been adequately evaluated to be used in place of the aPTT. Lepirudin, a recombinant hirudin, is no longer available.

Warfarin

Warfarin is impractical in the critical care setting. It is very long acting and associated with innumerable drug interactions. Although reversible with vitamin K, it is not immediately reversible. It is still used by some orthopedic surgeons as prophylaxis for total knee or hip arthroplasty is used less commonly since the advent of LMWH and DOACs (see “Anticoagulant Reversal”).

Aspirin

Aspirin has been studied for long-term secondary prevention of DVT/pulmonary embolism (PE). In this setting, it appears more effective than placebo but less effective than all other available anticoagulants drugs. While it is used in the setting of acute coronary syndromes and AF, it has no real role in the ICU patient with acute VTE.

Direct Oral Anticoagulants

DOACs inhibit either thrombin (factor IIa) or factor Xa. Thrombin is a serine protease and activates factors V, VIII, and XI and catalyzes the conversion of fibrinogen to fibrin, as well as stimulating platelet aggregation. Factor Xa is also a serine protease that represents the intersection of the extrinsic and the intrinsic coagulation pathways. It catalyzes the conversion of prothrombin to thrombin (see Figure 34–1).

Four DOACs are approved for use in the United States, including the Xa inhibitors rivaroxaban (Xarelto) and apixaban (Eliquis), and the direct thrombin inhibitor, dabigatran etexilate (Pradaxa). All 4 are approved for stroke prevention in non-valvular AF, as well as for treatment of established DVT and/or PE. Rivaroxaban and apixaban are also approved for prophylaxis for total hip and knee arthroplasty (Table 34–1). Others, including betrixaban could follow. The safety and efficacy of these drugs have not been studied for mechanical prosthetic heart valves and thus are not recommended in this setting.

A major advantage of these DOACs includes the lack of need for monitoring although this could be useful in emergencies. There is a marked reduction in drug interactions compared with warfarin, although cytochrome P450 (CYP) metabolism

is important for factor Xa inhibitor metabolism and P-glycoprotein (P-gp) metabolism affects the metabolism of all 4 of these agents. Renal metabolism also must be considered. Dosing for dabigatran, rivaroxaban, and apixaban, for treatment of established VTE and AF is outlined in Table 34–2 and the potential for drug interactions is further outlined in Table 34–3.

Large, randomized clinical trials in thousands of patients with AF and acute DVT and/or PE have been completed with these agents, indicating that they are at least as effective as warfarin. They appear to be at least as safe, and in some instances safer, with regard to bleeding.

Concomitant use of other drugs affecting hemostasis increases the risk of bleeding, including other anticoagulants, aspirin, other antiplatelet agents, thrombolytic agents, and nonsteroidal anti-inflammatory drugs.

Edoxaban

Edoxaban is the most recently approved direct factor Xa inhibitor in the United States. It is indicated to reduce risk of stroke and systemic embolism in patients with nonvalvular AF and for the treatment of DVT and PE following 5 to 10 days of initial

therapy with a parenteral anticoagulant (references 1 and 2 below). For AF, the recommended dose is 60 mg PO once daily. It should not be prescribed in patients when the CrCL is > 95 mL/min because of an increased risk of stroke compared with warfarin. The dose must be reduced to 30 mg once daily in patients with CrCl of 15 to 50 mL/min. In the nonvalvular AF trial, major bleeding occurred with a significantly lower incidence with edoxaban compared with warfarin. The endpoint of death or ICH also occurred in significantly fewer patients receiving edoxaban. Importantly, fatal bleeding and life-threatening bleeding occurred significantly less often with edoxaban, as did gastrointestinal bleeding with the lower dose. In contrast, the higher edoxaban dose led to more gastrointestinal bleeding than warfarin. For DVT and PE, the recommended dose is 60 mg once daily. The dose should be similarly reduced to 30 mg once daily for patients with CrCL 15 to 50 mL/min, body weight ≤ 60 kg, or in patients on certain P-gp inhibitors.

Dabigatran

Thrombin is a logical target for an anticoagulant. When it is activated from prothrombin, it converts soluble fibrinogen to insoluble fibrin, activates

TABLE 34–2 **Dosing of new oral anticoagulants for therapy of acute VTE and AF.**

Drug	Oral Dose	Renal Dosing	Heparin Bridge
Rivaroxaban (Xarelto)	VTE: 15 mg q 12h x 21 d, then 20 mg once daily AF: 20 mg once daily Take with food	Acute VTE: Do not use with marked renal impairment (CrCl < 30 mL/min) AF: For CrCl 15-50 mL/min, 15 mg orally, once daily	No
Apixaban (Eliquis)	10 mg q 12h x 1 wk, then 5 mg q 12h After at least 6 mo of therapy, decrease to 2.5 mg once daily	Acute VTE: No dose reduction AF: Decrease dose to 2.5 mg q 12h if any 2 of the following are present: -Creatinine ≥ 1.5 mg/dL -Age ≥ 80 -Weight ≤ 60 kg ESRD on HD: 5 mg q 12h; decrease dose to 2.5 mg q 12h if age ≥ 80 or weight ≤ 60 kg	No
Dabigatran (Pradaxa)	150 mg twice daily	All patients: CrCl < 30 mL/min with concomitant use of P-gp inhibitors: Do not use P-gp inducers (eg, rifampin): Do not use HD patients: No dosing recommendations can be offered Acute VTE: CrCl < 30 mL/min: Do not use CrCl < 50 mL/min with concomitant use of P-gp inhibitors: AF: CrCl 15-30 mL/min: 75 mg q 12h CrCl 30-50 mL/min with concomitant use of P-gp inhibitors: <ul style="list-style-type: none">• P-gp inhibitors dronedarone or ketoconazole: Consider reducing dose to 75 mg q 12h• Dose adjustment not necessary when coadministered with other P-gp inhibitors	Yes
Edoxaban (Savaysa)	60 mg once daily	Acute VTE: Reduce to 30 mg once daily for patients with CrCL 15 to 50 mL/min, body weight ≤ 60 kg, or in patients on certain P-gp inhibitors (see below). AF: Should not be prescribed when CrCL is > 95 mL/min. Reduce dose to 30 mg once daily in patients with CrCl of 15 to 50 mL/min.

TABLE 34–3 **New oral anticoagulants: drug interactions.^a**

Drug	
Rivaroxaban (Xarelto)	Concomitant use of rivaroxaban with combined P-gp and strong CYP3A4 inhibitors (eg, ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir, and conivaptan) should be avoided. Concomitant use of rivaroxaban with drugs that are combined P-gp and strong CYP3A4 inducers (eg, carbamazepine, phenytoin, rifampin, St. John’s wort) should also be avoided.
Apixaban (Eliquis)	If on strong dual CYP3A4/P-gp inhibitors (eg, ketoconazole, itraconazole, ritonavir, or clarithromycin): -If apixaban dose > 2.5 mg q 12h, decrease dose by 50% -If apixaban dose 2.5 mg q 12h, avoid coadministration If on strong dual CYP3A4/P-gp inducers (eg, rifampin, carbamazepine, phenytoin, St. John’s wort) avoid use.
Dabigatran (Pradaxa)	Concomitant P-gp inducers (eg, rifampin) should not be used. AF: With moderate renal impairment (CrCl 30-50 mL/min), reduce dose to 75 mg twice daily when administered concomitantly with the P-gp inhibitors dronedarone or systemic ketoconazole. Concomitant use of P-gp inhibitors in severe renal impairment (CrCl 15-30 mL/min) should be avoided. VTE: Avoid use with P-gp inhibitors in patients with CrCl in patients with CrCl < 50 mL/min
Edoxaban (Savaysa)	No dose reduction when P-gp inhibitors are coadministered. Avoid concomitant use of rifampin, a P-gp inducer.

CYP, cytochrome; P-gp, P-glycoprotein.
^aSee also Table 34–2 (regarding adjustments for renal dosing).

coagulation factors V, VIII, and XI, thus, generating more thrombin, and activates platelets. Dabigatran etexilate is a synthetic, orally available prodrug that is rapidly absorbed and converted by esterases to its active form, dabigatran, a potent direct inhibitor of both free thrombin and clot-bound thrombin. This drug has a rapid onset of action, very few drug interactions, no reported food interactions, and does not require routine coagulation monitoring.

Dabigatran is 35% bound to plasma proteins and is renally excreted, with 80% of the drug entering the urine unchanged. The anticoagulant effect accumulates in the setting of renal insufficiency, and such bioaccumulation correlates well with the degree of renal dysfunction.¹¹ In cases of moderate hepatic impairment, dabigatran can be administered safely and no dose adjustment is necessary.¹²

P-gp inhibition and renal insufficiency are major independent factors in increased exposure to dabigatran. There is no significant cytochrome P450 metabolism. Concomitant use of P-gp inhibitors in patients with renal impairment is expected to produce increased exposure of dabigatran compared to that seen with either factor alone (see Table 34–2). Absorption of dabigatran etexilate is mediated by P-gp; dabigatran etexilate is a substrate for P-gp, but active dabigatran is not. Thus, P-gp inhibitors can increase dabigatran absorption, increasing both area under curve (AUC) and C_{max} and P-gp inducers can reduce its absorption, resulting in inadequate levels. Concomitant P-gp inducers (eg, rifampin) should not be used in patients on dabigatran (see Table 34–3).

This drug is FDA approved for stroke prevention in patients with nonvalvular AF and for acute VTE at a dose of 150 mg twice daily. It is not approved, at present, for prophylaxis following total hip or knee replacement in the United States.

For AF, dabigatran was shown to be superior to dose-adjusted warfarin with a similar rate of major bleeding.¹³ A dose of 75 mg twice daily, is approved in the United States for patients with nonvalvular AF and severe renal insufficiency; that is, creatinine clearance (CrCl) of 15 to 30 mL/min.

Over 9000 patients were evaluated in studies involving dabigatran leading to the approval of this drug for the treatment of acute VTE, including RE-COVER, RE-COVER II, RE-MEDY, and RE-SONATE.^{14–16} The first 2 studies were initial VTE therapy studies utilizing a parenteral anticoagulant

bridge. Dabigatran proved effective standard therapy, and while major bleeding rates were similar, there were fewer episodes of nonmajor bleeding with dabigatran than with warfarin. There was, however, a higher rate of gastrointestinal (GI) bleeding.^{14,15} The extension studies in patients who had completed a course of anticoagulation demonstrated not surprisingly, that extended duration of anticoagulation with dabigatran was noninferior to warfarin but superior to placebo in reducing recurrent VTE. Based on the way these clinical trials were conducted, for acute VTE, the parenteral anticoagulant bridge is required for 5 to 10 days prior to oral dabigatran alone. Dabigatran is rated pregnancy category C.

Rivaroxaban

Factor Xa represents the rate-limiting factor in thrombin generation and amplification, generating the Xa complex that converts prothrombin to thrombin. The direct factor Xa inhibitors inhibit free factor Xa, factor Xa in the prothrombinase complex, and factor Xa found in clots, and this is independent of antithrombin. In contrast, LMWHs, UFH, and fondaparinux, are dependent on antithrombin to inhibit factor Xa.

Clearance of this drug is decreased to some extent in patients with renal impairment, but two-thirds of its primary mode of clearance is nonrenal. While approximately 67% of rivaroxaban is eliminated by the kidney, half of this is clearance of active drug and half of it is clearance of inactive rivaroxaban, which is not clinically important. CYP450, P-gp and breast cancer-related protein (BCRP) are all involved with metabolism. It is 93% protein bound and thus, not dialyzable. Rivaroxaban is a substrate of CYP3A4/5, CYP2J2, and the P-gp and ATP-binding cassette G2 (ABCG2) transporters. Inhibitors and inducers of these CYP450 enzymes or transporters, such as P-gp, may result in changes in rivaroxaban exposure.

Concomitant use of rivaroxaban with combined P-gp and strong CYP3A4 inhibitors (eg, ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir, and conivaptan) should be avoided. In addition, concomitant use of rivaroxaban with drugs that are combined P-gp and strong CYP3A4 inducers (eg, carbamazepine, phenytoin, rifampin, St. John's wort) should also be avoided (see Tables 34–2 and 34–3).

For stroke prevention, the randomized, double-blinded ROCKET AF trial found that rivaroxaban 20 mg daily (15 mg daily if CrCl is 15-50 mL/min) was noninferior to warfarin in efficacy, with no significant difference in major bleeding events.¹⁷ Due to high plasma protein binding (> 90%), rivaroxaban is not eliminated during hemodialysis.

The Einstein DVT and PE studies (> 8000 patients) led to FDA approval for rivaroxaban for the treatment of established DVT and/or PE.^{18,19} These large prospective, randomized trials demonstrated noninferiority to warfarin with regard to recurrent VTE, and in the PE study, the risk of major bleeding was significantly lower. For acute VTE, the drug is dosed as 15 mg q12h for 3 weeks and then 20 mg once daily. Unlike in AF, where the dose can be reduced with a CrCl of 15 to 50 mL/min, this has not been recommended in VTE. However, in acute VTE with CrCl less than 30 mL/min, the drug should not be used (see Table 34-2).

Rivaroxaban is also approved in the United States for VTE prophylaxis after hip or knee replacement surgery based on superiority over enoxaparin, and at least comparable safety. At present, however, no NOAC is approved specifically for VTE prophylaxis in the ICU.

When changing from warfarin, rivaroxaban should be initiated when the INR is less than or equal to 3. Finally, tablets may be crushed and either mixed in applesauce or suspended in water and administered via an nasogastric (NG) tube to appropriate patients who have difficulty swallowing a whole tablet. This drug is pregnancy category B and should be used during pregnancy only if the potential benefit outweighs the potential risk to the mother and the fetus.

Apixaban

Like rivaroxaban, apixaban is FDA approved for stroke prevention in AF, acute VTE, and for prophylaxis in total knee and hip replacement. Apixaban is an oral, direct factor Xa inhibitor that is highly bioavailable (80%), is highly protein bound, and reaches peak plasma concentration within 2 to 3 hours after intake. It is 75% hepatically metabolized with the rest renally excreted. Dosing including renal dosing is outlined in Table 34-2. No dose adjustment is required in patients with mild hepatic impairment.

It has the least renal dependence of the three FDA-approved NOACs and has limited drug interactions. While there is minimal CYP3A4 metabolism,

the drug does have potential interactions with potent CYP3A4 inhibitors. For patients on doses of apixaban greater than 2.5 mg twice daily, the dose should be decreased by 50% when it is administered with drugs that are strong dual inhibitors of CYP3A4 and P-gp (eg, ketoconazole, itraconazole, clarithromycin, or ritonavir). For patients receiving a dose of 2.5 mg twice daily, strong dual inhibitors of CYP3A4 and P-gp should be avoided (see Table 34-3).

In the setting of nonvalvular AF, the ARISTOTLE trial demonstrated that apixaban was superior to dose-adjusted warfarin in preventing stroke and systemic embolism. There was a lower rate of bleeding complications, and a lower mortality.²⁰ In the AVERROES trial, apixaban 5 mg twice daily was compared with aspirin (81-325 mg) for stroke prevention.²¹ There was a lower risk of stroke with apixaban but, interestingly, no difference in the bleeding rate compared with aspirin.

FDA approval of apixaban for acute DVT/PE was based on 2 large, prospective, phase 3 trials, AMPLIFY²² and AMPLIFY-EXTENSION.²³ There was no 5 to 10 day heparin bridge required. Apixaban proved noninferior to standard therapy with LMWH followed by warfarin with regard to recurrent VTE events, and was associated with significantly less major bleeding, and less clinically relevant nonmajor bleeding than standard therapy. The FDA-approved dose of apixaban for the treatment of acute DVT and/or PE is 10 mg twice daily for 1 week followed by 5 mg twice daily. Based on the extension study, a dose of 2.5 mg twice daily is indicated to reduce the risk of recurrent DVT and PE following initial 6 months treatment for DVT and/or PE.

In the setting of total joint replacement, apixaban is administered as 2.5 mg orally 12 to 24 hours after surgery. For hip replacement, the dose is 2.5 mg twice daily for 35 days and for total knee replacement (TKR), the dose is 2.5 mg po twice daily for 12 days. As noted, none of the NOACs are approved for use as prophylaxis other than TKR and total hip replacement (THR). Importantly for ICU patients, when patients cannot swallow whole tablets, 5 mg and 2.5 mg apixaban tablets may be crushed and suspended in 60 mL D₅W and immediately administered through a nasogastric tube. There are no data regarding crushed and suspended apixaban tablets swallowed by mouth. Like rivaroxaban, apixaban is pregnancy category B.

Anticoagulant Monitoring for Novel Oral Anticoagulants

The NOACs do not require routine monitoring in the setting of AF, acute VTE, or in the setting of VTE prophylaxis. However, it is important to check coagulation tests when a patient is admitted to the ICU on a NOAC, particularly if it is unclear whether or not the patient has been taking one. This may also be useful if there is bleeding or a high risk of bleeding. Thus, coagulation assays are not helpful in adjusting doses of NOACs but may help determine whether there is significant ongoing anticoagulant effect. With acute bleeding, or with emergency invasive surgical procedure, this is particularly important.

Dabigatran catalyzes the conversion of fibrinogen to fibrin, and thus, results in prolongation of most routine coagulation assays except the prothrombin time (PT). The ecarin clotting time is useful but less widely available. Because the thrombin time increases linearly with increasing dabigatran concentration, it seems intuitive that this measurement would provide the best direct assessment of thrombin activity. However, the thrombin time is overly sensitive to dabigatran levels and may be prolonged in the setting of a clinically insignificant dabigatran effect. The dilute thrombin time (Hemoclot assay) has very good linear correlation to plasma levels of dabigatran and is probably the most reliable method to measure the anticoagulant effect of dabigatran.²⁴ The aPTT can also be used; however, the relationship between dabigatran concentration and the aPTT is nonlinear and so is less reliable. A normal aPTT will likely indicate the absence of a clinically important anticoagulant effect. It is crucial to develop additional laboratory studies to correlate coagulation assay results with plasma levels of dabigatran.

Rivaroxaban and apixaban directly inhibit factor Xa, complexing with factor Va, independent of antithrombin. An increased PT tells us it is likely there is rivaroxaban in the bloodstream. There is less effect on the aPTT. A specific assay has been developed for direct Xa inhibitors that differs from the anti-Xa assay used to monitor LMWH, and this could potentially provide an effective method to determine the effect of rivaroxaban.²⁵ More data are needed, however. At present, there is no precise means by which to accurately assess the degree of anticoagulation in a patient on an Xa inhibitor.

Surgery and Procedures in the Critically Ill Patient

When urgent or emergent procedures arise, there are a number of potential anticoagulant considerations. The risk/benefit of anticoagulant discontinuation depends on the reason the patient is anticoagulated, the bleeding risk imparted by the procedure, and concomitant comorbidities. A patient with submassive or massive acute PE with another life-threatening condition requiring immediate surgery should simply have an inferior vena cava filter (IVCF) placed and have anticoagulation discontinued. Patients should be individualized.

As described earlier, neither the aPTT nor PT can determine the anticoagulant effects of dabigatran, rivaroxaban, or apixaban at any given time. A normal aPTT suggests that hemostatic function is not impaired by dabigatran, and a normal PT or lack of antifactor Xa activity would indicate that hemostatic function is not impaired on rivaroxaban or apixaban. Thus, these tests are useful when upcoming surgical procedures impart a significant bleeding risk. A normal thrombin time excludes a significant dabigatran effect; this measurement may be useful when a high-risk procedure is emergent.

Dabigatran is primarily renally eliminated so the timing of discontinuation should be based on the CrCl and the bleeding risk associated with the procedure. The pharmacodynamic effect of dabigatran declines in parallel with its plasma concentration, so surgery may only need to be delayed for about 12 hours after the last dabigatran dose.

If the CrCl is 31 to 50 mL/min, the last dose of dabigatran should be at least 48 hours before the procedure for low-risk surgery, and even longer (consider 4 days) before a procedure that poses a high risk of bleeding.¹¹ Mild or moderate renal impairment would appear to be of less concern in patients on rivaroxaban, in whom a decreased CrCl appears to have a more limited effect on the half-life of the drug, but it should still be considered when stopping the drug preoperatively.

A large nonrandomized study examined perioperative bleeding rates from 7 days prior until 30 days after invasive procedures for patients on warfarin or dabigatran.²⁶ The procedures included pacemaker/defibrillator insertion, dental procedures, diagnostic

procedures, cataract removal, colonoscopy, and joint replacement. The last dose of dabigatran was given a mean of 49 hours (range 35-85) before the procedure, compared to 114 hours (range 87-144) for the last preprocedure dose of warfarin ($P < 0.001$). There was no significant difference in the rates of periprocedural major bleeding between the drugs. Among patients having urgent surgery, major bleeding occurred in 21.6% with warfarin, 17.7% with dabigatran at 150 mg, and 17.8% with dabigatran at 110 mg.²⁶

While there are no large studies examining perioperative bleeding rates in patients receiving rivaroxaban or apixaban, the same general principles should apply with regard to procedure bleeding risk and drug elimination based on the characteristics of these drugs. It should be recognized that these guidelines are approximate and that patients should be carefully scrutinized based on the specific procedure, perceived bleeding risk, and comorbidities including renal function.

For rivaroxaban and apixaban, it appears acceptable to delay low-risk surgery for approximately 24 hours after the previous dose. When the bleeding risk is higher, 48 hours would appear to be safer. With a more significant decrease in CrCl (ie, < 30 mL/min), an approximately 4 day delay would be appropriate. Resumption of a NOAC in a low bleeding risk scenario should be at least 24 hours after the procedure. The European Society of Anaesthesiology and the French Study Group on Thrombosis and Hemostasis have published recommendations about perioperative management of NOACs.^{27,28}

The general principles described above also apply to neuraxial anesthesia but it should be realized that bleeding in this setting has tremendous implications. Catheter placement should be considered when the anticoagulant level is at its trough and while removal may be less critical; it should also be timed as carefully as possible. At least 2 half-lives should be allowed to pass before catheter removal, at which point only 25% of the drug remains active. Patients should be monitored carefully for bleeding after catheter removal. Recommendations for the use of the NOACs in the setting of neuraxial anesthesia have been proposed by Llau and colleagues based on existing guidelines and the pharmacokinetics of each drug.²⁹

Anticoagulant Reversal

With the much shorter half-lives of the NOACs, discontinuing a NOAC and providing supportive care may be all that is required depending on the type and severity of the bleed, or whether an invasive procedure can be delayed. The half-life of dabigatran after multiple doses is approximately 14 to 17 hours and is not dose dependent; if there is no active bleeding after an overdose, stopping the drug may be sufficient. The shorter half-life proven in younger healthy patients on rivaroxaban or apixaban compared with elderly patients may also be favorable with regard to simply stopping the drug.

When a bleeding event occurs, initial measures include control of the bleeding site, volume resuscitation with fluids and/or packed red blood cells, as well as determination of the source of bleeding. Minor bleeding such as epistaxis, or other mucosal or superficial bleeding can often be managed symptomatically with compression/nasal packing and drug discontinuation. Gastrointestinal bleeding is managed by anticoagulant discontinuation, blood transfusion as needed, and aggressive endoscopic and other specific therapy. Life-threatening bleeding including intracerebral hemorrhage (ICH) requires not only withdrawal of the anticoagulant and supportive measures but also ICU transfer and potentially interventional procedures as well as consideration for reversal. Nonspecific reversal agents can be considered in patients with major or life-threatening bleeding.^{30,31}

Warfarin and other VKAs may be reversed with vitamin K and/or FFP. Reversal is not instantaneous. Four-component PCCs are recommended in recent guidelines.²⁸ Four-factor PCC is FDA approved for use in the United States for warfarin reversal in the setting of severe bleeding.

In the case of overdose with an anticoagulant, activated charcoal may prevent additional oral drug absorption when administered within 1 to 2 hours of ingestion. The minimal data available suggest that activated charcoal may be useful in dabigatran and apixaban overdose or accidental ingestion, and probably this applies to rivaroxaban as well.^{32,33} Hemodialysis may reverse the anticoagulant effects of dabigatran overdose in severe bleeding because only about 35% of dabigatran is bound to plasma

proteins.¹¹ Rivaroxaban and apixaban are highly protein bound (95% and 87%, respectively) precluding removal with dialysis.

While FFP is frequently administered for initial control of bleeding in anticoagulated patients, its use as a NOAC reversal agent has not undergone detailed evaluation in humans. The 2011 American College of Cardiology Foundation/American Heart Association guidelines recommended that severe bleeding from dabigatran merits transfusion of FFP, packed red cells, and surgical intervention as appropriate.³⁴ Studies in mice suggest that FFP may help limit ICH hematoma expansion.³⁵ In humans, data are inadequate to support the use of FFP in ICH caused by dabigatran.

While FFP may be useful in cases of coagulation factor depletion, it is not generally effective in reversing bleeding resulting from inhibition of coagulation factors.³⁰ However, it may be that delivery of clotting factors may overwhelm an ongoing inhibitory effect (see “Nonspecific Reversal Agents”). Still, overall, FFP remains controversial based on a lack of clear supportive data.

Specific NOAC Reversal Agents

Idarucizumab is a monoclonal antibody fragment that binds dabigatran with an affinity that is 350 times higher than that observed with thrombin. (REF 1 BELOW) Thus, this drug binds free and thrombin-bound dabigatran and neutralizes its activity (SAME REF 1 AS BELOW). In a clinical trial leading to FDA approval, idarucizumab completely reversed the anticoagulant effect of dabigatran within minutes.

Andexanet alfa is a novel recombinant, modified factor Xa molecule that acts as a factor Xa decoy that binds and sequesters direct Xa inhibitors in the blood (REF 2 BELOW). The native factor Xa is then be available to participate in the coagulation process and restore hemostasis. In a preliminary report of an ongoing cohort study in patients with acute major bleeding associated with the use of factor Xa inhibitors, andexanet rapidly reversed anti-factor Xa activity and was not associated with serious side effects (SAME REF 2 AS BELOW). Effective hemostasis was achieved 12 hours after an infusion of andexanet in 79% of the patients. Thrombotic events occurred in 18% of the patients in the safety population. Additional data are pending as is consideration for FDA approval.

Finally, another agent, ciraparantag (PER977), is being evaluated as a more universal anticoagulant reversal agent (REF 3 BELOW). This is small, synthetic, water-soluble, cationic molecule is designed to bind specifically to unfractionated heparin and LMWH through noncovalent hydrogen bonding and charge–charge interactions. This drug binds in a similar way to the new oral factor Xa inhibitors and to dabigatran.

Nonspecific Reversal Agents

Nonspecific agents have been used for reversal of major bleeding in this setting^{37,38}; however, more data are needed. Recombinant factor VIIa (NovoSeven) initiates thrombin generation by activating factor X. Prothrombin complex concentrates were originally utilized for treating patients with hemophilia B. More recently, data have been published related to the treatment of VKA-related bleeding for their ability to rapidly and effectively correct the INR. These preparations are concentrated solutions derived from human plasma containing coagulation factors II, IX, X, and/or VII. They exist as either 3-factor or 4-factor PCCs depending on their factor VII content. Three-factor PCCs contain the inactivated vitamin K–dependent coagulation factors II, IX, and X, with minimal to no factor VII. Four-factor PCCs contain the same 3 coagulation factors with inactivated factor VII concentrations similar to their factor IX content. Thus, thrombin formation is stimulated. Both 3-factor and 4-factor PCCs have been studied in major bleeding with VKAs, although none have been compared head-to-head.

There is only one 4-factor PCC available in the United States, marketed under the name Kcentra (marketed as Beriplex P/N in 25 other countries) and the only PCC in the United States that is FDA-approved indication for the urgent reversal of acquired coagulation factor deficiency in the setting of vitamin K–related acute major bleeding. In addition to clotting factors, it also contains proteins C and S, antithrombin III, human albumin, and heparin. In view of the latter, it is contraindicated in HIT.³⁹

There are two 3-factor PCCs available in the United States—Profilnine SD and Bebulin. Another PCC, an activated PCC (aPCC, also referred to as anti-inhibitor coagulant complex) is available in the United States under the name FEIBA NF. It differs from other PCCs in that it contains inactivated

factors II, IX, and X and small amounts of activated factor VII; this combines the effect of both recombinant factor VIIa and 4-factor PCC.

van Ryn and colleagues found that recombinant factor VIIa and activated prothrombin complex concentrate may be potential antidotes for dabigatran-induced severe bleeding in humans.³⁸ Marlu and associates determined that activated prothrombin complex concentrate as well as 4-factor PCC could be reasonable antidotes to dabigatran and rivaroxaban.³⁷

Thus far, it appears that 3-factor PCC products may be less effective than 4-factor PCCs in reversing elevated INRs in patients with warfarin overdose, but more data are needed for the NOACs. Finally, more data are needed with regard to the thrombotic risk associated with the use of these nonspecific prohemostatic agents.

SUMMARY AND THE FUTURE

Critically ill patients continue to require careful consideration with regard to anticoagulation and bleeding risk. Parenteral anticoagulants are favored in the ICU and we have substantial experience with these agents with regard to monitoring, perioperative dosing, and reversal. The NOAC era is upon us. The learning curve remains steep. Renal dosing and drug interactions must be considered. As with LMWHs, antifactor Xa activity monitoring may become a more available validated means of testing for exposure to rivaroxaban and apixaban. Newer assays derived from INR testing may become more useful methods to monitor NOACs. More studies are needed to examine reversal.

Acute Abdominal Dysfunction

35

Vanessa P. Ho, MD, MPH and
Philip S. Barie, MD, MBA, FIDSA, FCCM, FACS

KEY POINTS

- 1 Causes of acute abdominal pathology in the intensive care unit (ICU) patient include acute acalculous cholecystitis (AAC), severe acute pancreatitis, feeding intolerance, paralytic ileus and diarrhea, and abdominal compartment syndrome (ACS).
- 2 An emergent bedside laparotomy may be indicated for patients with a high suspicion for intra-abdominal pathology; however, this is a high-risk procedure, requires substantial resources to be mobilized, and has a risk of mortality.
- 3 Modern management of pancreatic necrosis and infected necrosis, known as the “step-up” approach, consists of initial medical management with fluid resuscitation and antibiotic administration, followed by percutaneous catheters for drainage of infected fluid.
- 4 Feeding intolerance in the critically ill patient can be attributable to the patient’s critical illness, medications, intra-abdominal pathology, or underlying disease.
- 5 Treatment and management of ACS consists of serial monitoring of intra-abdominal pressures (IAP); optimization of systemic perfusion and organ function in the presence of intra-abdominal hypertension (IAH); institution of medical procedures to decrease IAP and reduce end-organ dysfunction; and prompt surgical decompression for refractory IAH or ACS.

INTRODUCTION

Critically ill patients are susceptible to a variety of causes and manifestations of abdominal dysfunction. However, the diagnosis and treatment of these conditions can be challenging secondary to nonspecific clinical findings, concurrent complex disease processes, and altered mental status. The purpose of this chapter is to discuss select causes of abdominal dysfunction in the critically ill patient, including evaluation for acute abdominal pathology in the critically ill patient, AAC, severe acute pancreatitis, feeding intolerance, paralytic ileus and diarrhea, ACS, and care of the long-term open abdomen.

Evaluation for Acute Abdominal Pathology in the Intensive Care Unit

Critically ill patients are susceptible to acute abdominal pathology, including bowel perforation, biliary tract disease, pancreatitis, ischemia, and hemorrhage. Acute abdominal pathology may be the patient’s initial insult, or the patient may develop abdominal dysfunction as a complication of critical illness. Patients with recent surgery may manifest intra-abdominal complications such as anastomotic leak or abscess, or may develop iatrogenic abdominal complications such as bowel perforation from paracentesis, or pancreatitis after endoscopic

retrograde cholangiopancreatography (ERCP). Critically ill patients may pose a diagnostic dilemma, as some patients may be challenging to evaluate due to concomitant critical illness; even patients with evaluable mental status may have unreliable clinical examinations. Steroid use and immunosuppression may blunt a patient's clinical examination even in the presence of an intra-abdominal catastrophe. Evaluation of the patient with suspicion for acute abdominal pathology should occur expeditiously; failure to consider the abdomen as a potential source of sepsis or hemorrhage can lead to missed diagnoses and poor outcomes.

Although physical examination findings in this population can be nonspecific, patients with unexplained sepsis or abdominal pain (if they can communicate same) should undergo a thorough physical examination to evaluate for abdominal distension, tenderness, and inspection of all wounds and incisions. Laboratory findings will be nonspecific as well, but may provide important clues to the diagnosis and should be obtained and trended; white blood cell count, liver enzymes, amylase, lipase, lactate, and arterial blood gases may be of value.

Evaluation of the abdomen in the critically ill patient should include diagnostic radiologic imaging if clinically tolerable (in terms of positioning, or the need to transport the patient to the radiology suite) and appropriate for the suspected underlying process.¹ In general, computed tomography (CT) is the test of choice for patients with a suspected intra-abdominal source of sepsis. Pancreatitis, diverticulitis, and other inflammatory bowel processes; intra-abdominal abscesses; and bowel obstructions are visualized easily with contrast-enhanced CT. Patients with recent abdominal surgery and postoperative intra-abdominal infection typically manifest signs and symptoms of dehiscence, leak, or abscess after 5 to 10 days and CT scan can be instrumental for the diagnosis; CT scans performed earlier than 5 to 7 days in postoperative patients are of limited value due to identification of nonspecific abdominal fluid, inflammation, and even residual pneumoperitoneum introduced during celiotomy. CT scans are sensitive for detecting the presence of air, which can be pathologically located outside the bowel in the peritoneal cavity, within the bowel wall (pneumatosis intestinalis), or in the portal venous system.

In order to obtain the most useful images, both oral and intravenous contrast should be utilized. Oral contrast allows differentiation of the intraluminal bowel fluid from extraluminal fluid collections and will help to identify the transition point in cases of bowel obstruction. Intravenous contrast optimizes visualization of infectious processes by highlighting areas of inflammation; additionally, intravenous contrast aids in the assessment of solid organs and areas of potential ischemia or hemorrhage. Intravenous contrast is especially useful in cases of acute pancreatitis to delineate areas of devitalized or necrotic pancreatic tissue or retroperitoneal fat. Allergy or the patient's renal function may limit the ability to utilize intravenous contrast.

Specific conditions may require targeted diagnostic evaluation. Patients with a suspected biliary infection may benefit more from ultrasound (US) evaluation of the abdomen, rather than CT scan. Calculous or acalculous cholecystitis or dilation of bile ducts can be evaluated easily with US. Patients with gastrointestinal bleeding or suspicion of ischemic colitis or *Clostridium difficile* infection would benefit from endoscopy. Endoscopy for bleeding can be both diagnostic and therapeutic and can be performed at the bedside if necessary. Angiography with interventional radiology techniques can also be diagnostic and therapeutic for arterial bleeding.

Patients who are too unstable hemodynamically or clinically for imaging pose a greater diagnostic predicament. Patients requiring multiple or increasing doses of vasopressors, patients with ongoing hemorrhage, or patients with severely compromised respiratory status may have excess or unacceptable risk of morbidity from transport to radiology for testing.² These patients should be given goal-directed resuscitation and stabilized with fluids and antibiotics if possible and imaged when feasible. For patients with a high suspicion for intra-abdominal pathology, an emergent bedside laparotomy may be indicated; however, this is a high-risk procedure, requires substantial resources to be mobilized, and has a risk of mortality. Other described diagnostic options for these patients include diagnostic peritoneal lavage (DPL), which places a catheter through the abdominal wall into the peritoneal cavity to allow evaluation of peritoneal fluid; some centers also advocate bedside diagnostic laparoscopy. These techniques have

been used in the ICU to evaluate the abdomen for otherwise unevaluable patients with some success, but are not yet standard of care.^{1,3,4}

Acute Acalculous Cholecystitis

AAC is the development of acute inflammation of the gallbladder in the absence of gallstones. AAC is generally considered to be a complication of serious medical and surgical illnesses, especially in the setting of trauma, burns, sepsis, prolonged fasting, or total parenteral nutrition. Among medical patients, a variety of systemic diseases have been associated with the development of AAC such as diabetes mellitus, abdominal vasculitis, congestive heart failure, and cholesterol embolization of the cystic artery. Resuscitation from hemorrhagic shock or cardiac arrest has been associated with AAC.^{5,6} Acalculous cholecystitis may also develop as a secondary infection of the gallbladder during systemic sepsis for a wide range of infections.

AAC poses major diagnostic challenges. Most afflicted patients are critically ill and unable to communicate their symptoms. Cholecystitis is but one of many potential causes in the differential diagnosis of systemic inflammatory response syndrome (SIRS) or sepsis in such patients. Rapid and accurate diagnosis is essential, as gallbladder ischemia can progress rapidly to gangrene and perforation. Acalculous cholecystitis is sufficiently common that the diagnosis should be considered in every critically ill or injured patient with a clinical picture of sepsis or jaundice and no other obvious source.

US and CT are generally useful for the diagnosis of AAC. Ultrasound of the gallbladder is generally the first-line modality for the diagnosis of AAC in the critically ill patient as it is rapid, low risk, and portable. In calculous cholecystitis, US is useful for detecting gallstones and measuring bile duct diameter; in AAC, these measurements are not valuable. Thickening of the gallbladder wall is the single most reliable criterion, with reported specificity of 90% at 3 mm and 98.5% at 3.5-mm wall thickness, and sensitivity of 100% at 3 mm and 80% at 3.5 mm.⁷ Accordingly, gallbladder wall thickness greater than or equal to 3.5 mm is generally accepted to be diagnostic of AAC. Other helpful US findings for AAC include pericholecystic fluid or the presence of intramural gas or a sonolucent intramural

layer, or “halo,” that represents intramural edema. Distension of the gallbladder of more than 5 cm in transverse diameter has also been described.^{6,7} False-positive US examinations may occur in particular when conditions including sludge, nonshadowing stones, cholesterosis, hypoalbuminemia, or ascites mimic a thickened gallbladder wall. CT appears to be as accurate as US in the diagnosis of AAC. Diagnostic criteria for AAC by CT are similar to those described for US. Low cost and the ability to perform US rapidly at the bedside make it the preferred diagnostic modality in possible AAC in the ICU setting. Preference may be given to CT if other thoracic or abdominal diagnoses are under consideration.

Historically, the treatment for AAC was cholecystectomy, owing to the ostensible need to inspect the gallbladder and perform a resection if gangrene or perforation was discovered. In the modern era, percutaneous cholecystostomy can be a lifesaving, minimally invasive approach, as it controls the AAC in 70% to 90% of patients.^{8,9} For this procedure, the gallbladder is intubated under US (occasionally laparoscopic) guidance via an anterior or transhepatic approach (through the right hepatic lobe) in order to minimize leakage of bile. Rapid improvement should be expected when percutaneous cholecystostomy is successful. Percutaneous treatment is an especially useful modality in the elderly patient with sepsis or patients who are unstable for a surgical procedure. Cholecystostomy will not decompress the common bile duct if cystic duct obstruction is present, therefore the common duct must be decompressed in addition by some manner (eg, ERCP) with sphincterotomy, or laparoscopic or open common bile duct exploration if cholangitis is suspected.

If percutaneous cholecystostomy does not lead to rapid improvement, the tube may be malpositioned, not draining properly, or the patient may have gangrenous cholecystitis. Other reported causes of failure include catheter dislodgement, bile leakage with peritonitis, or an erroneous diagnosis. Perforated ulcer, pancreatic abscess, pneumonia, and pericarditis have been discovered in the aftermath of percutaneous cholecystostomy when patients failed to improve. Reported major complications occur after 8% to 10% of procedures, including dislodgment of the catheter, acute respiratory distress syndrome (ARDS), bile peritonitis,

hemorrhage, cardiac arrhythmia, and hypotension due to procedure-related bacteremia.^{8,9} A cholecystostomy or cholecystectomy may be required if other sources of sepsis are ruled out and the patient continues to deteriorate. If an operation is warranted, open cholecystostomy may be accomplished under local anesthesia through a short right subcostal incision, but the ability to visualize elsewhere in the abdomen is limited. A laparotomy or laparoscopy would be required to drain distant fluid collections or identify other pathology that may mimic acute cholecystitis in the case of a misdiagnosis (eg, perforated ulcer, cholangitis, pancreatitis). In stable patients with AAC who require surgery, laparoscopic cholecystectomy has been described.

Antibiotic therapy does not substitute for drainage of AAC, but is an important adjunct. The most common bacteria isolated from bile in acute cholecystitis are *Escherichia coli*, *Klebsiella* spp., and *Enterococcus faecalis*, although prior antibiotic administration may allow for other opportunistic pathogens to be present.⁵ However, critical illness and prior antibiotic therapy alter host flora, and resistant or opportunistic pathogens may be encountered. Anaerobes are particularly likely to be isolated from bile of patients with diabetes mellitus, in those older than 70 years, and from patients whose biliary tracts have been instrumented previously.

Patency of the cystic duct can be determined immediately after the cholecystostomy is performed by tube cholangiography. This should be performed again after the patient has recovered to determine the presence of gallstones that may not have been detected initially. If gallstones are present, an elective cholecystectomy is usually recommended, with the drainage tube remaining in place during the interprocedure interval. For patients without gallstones, interval cholecystectomy is usually not indicated, and the cholecystostomy tube can be removed 4 to 6 weeks postcholecystostomy after tube cholangiography confirms that gallstones are absent. Recurrent episodes warrant cholecystectomy.

Acute Pancreatitis

Acute pancreatitis can vary in presentation from mild to severe. Patients with severe acute pancreatitis often require a prolonged ICU stay to provide supportive therapy as patients may develop sepsis

and progressive organ failure. The pancreas can develop focal or diffuse areas of nonviability, known as necrotizing pancreatitis; when bacteria from the gut infiltrate the nonviable tissue, it becomes infected necrosis. Whereas mild acute pancreatitis has a low mortality rate and usually resolves after a short period of bowel rest, mortality from severe acute pancreatitis with sterile necrosis is estimated to be 10% and can be as high as 70% in the presence of infected pancreatic necrosis.^{10,11}

Acute pancreatitis typically presents with epigastric pain that radiates to the back or shoulder, concomitant with nausea, vomiting, fever, and leukocytosis. Laboratory evaluation should include a complete blood count, a complete metabolic panel with liver enzymes, amylase, lipase, and lactate dehydrogenase. For diagnosis of pancreatitis, amylase has a higher sensitivity and lipase has higher specificity; levels greater than 3 times the upper limit of normal support the diagnosis. However, the magnitude of elevation of these laboratory values does not correlate with severity of illness; similarly, normalization of values does not signify resolution of disease. Concurrently elevated liver enzymes, especially alanine aminotransferase, can suggest a biliary etiology.

The most important first step in evaluation of patients with pancreatitis is to identify risk of progression to severe pancreatitis so that aggressive treatment can be instituted expeditiously. Multiple scoring systems exist that are designed to assess the disease severity, although no one system is universally accepted as superior. Common scoring systems include the Ranson criteria, Acute Physiology and Chronic Health Evaluation (APACHE)-II, and the CT severity index (also known as the Balthazar score) (Table 35–1). Although the Ranson criteria were first described in 1974, the score remains clinically useful. Early CT scans for prognostic reasons are not indicated in patients with pancreatitis, as early imaging lacks sensitivity to detect necrosis and infected necrosis is not typically present early in the course of the disease. Patients who develop persistent SIRS or clinical deterioration after 72 hours may benefit from further characterization of disease by CT.

The initial treatment of severe acute pancreatitis is supportive and includes aggressive fluid resuscitation, pain control, and supplemental oxygen administration. A substantial inflammatory response leads to

TABLE 35–1 Severe acute pancreatitis scoring systems.

System	Criteria	Scoring and Interpretation
Ranson criteria	<p>On admission</p> <ol style="list-style-type: none"> 1. Age > 55 2. WBC > $16 \times 10^9/L$ 3. LDH > 350/L 4. AST > 250/L 5. increased vascular permeability and fluid sequestration within the intra-abdominal space. Resuscitation should target adequate end-organ perfusion to maintain acceptable physiologic targets such as blood pressure, heart rate, and urine output. Patients with severe acute pancreatitis are at risk for development of multiple organ dysfunction syndrome (MODS); acute respiratory failure, circulatory shock, and

acute kidney injury are observed in severe cases. In extremely ill patients, central venous pressure and mixed venous oxygen saturation may be of additional value. Sequential bladder pressure measurements are advisable to monitor for ACS.

Historically, a mainstay of treatment for severe acute pancreatitis was bowel and pancreatic rest, as pancreatic stimulation from enteral nutrition was

believed to exacerbate pancreatic inflammation. Accordingly, patients with severe acute pancreatitis were given parenteral nutrition until the pancreas recovered. However, over the last decade, several randomized controlled trials comparing enteral to parenteral nutrition have demonstrated that enteral nutrition is associated with decreased infectious morbidity, shorter length of stay, fewer overall complications, and faster resolution of the disease process.¹² Accordingly, enteral nutrition is preferred over parenteral nutrition. Enteral nutrition should be administered early; while the exact timing for initiating enteral nutrition is unknown, it is currently believed that feeding should be commenced soon after admission. Delays in initiation of enteral nutrition can lead to prolonged ileus and decrease tolerance to feeding; additionally, small studies suggest that the benefits of enteral nutrition may be reduced if the enteral nutrition is delayed. The preferred route of enteral administration is also unknown; several trials have failed to detect a difference between nasogastric and nasojejunal feeding.¹¹ It has been suggested that probiotics could protect patients from overwhelming sepsis from opportunistic pathogens. Ultimately, probiotics have not proved to be effective and may actually increase mortality; routine administration of probiotics is not recommended.¹³

The most common cause of death from severe acute pancreatitis is MODS that develops as a result of infected pancreatic necrosis. This led to the hypothesis that antibiotic prophylaxis for patients with pancreatic necrosis might prevent the later sequelae and morbidity of infection. Early studies in the 1990s showed lower rates of infected pancreatic necrosis with lower mortality; subsequently, administration of antibiotics for prophylaxis became common.^{14,15} More recently, 3 double-blind randomized trials were published that could not confirm any beneficial effects of antibiotic prophylaxis; these well-done studies showed that prophylaxis is not associated with a statistically significant reduction in mortality, in the incidence of infected pancreatic necrosis, in the incidence of nonpancreatic infections, or in need for surgical interventions.¹⁶⁻¹⁸ Therefore, antibiotic prophylaxis for severe acute pancreatitis is not recommended.

It can be challenging clinically to differentiate if a severe SIRS response from active infection of

pancreatic necrosis as patients will appear ill in both circumstances. Patients suspected of having infected necrosis should have the tissue sampled for culture via percutaneous fine-needle aspiration. Patients with infected necrosis should have antibiotic treatment and management of the infected tissue.

Traditionally, open debridement with pancreatic necrosectomy was performed to remove infected tissue but this procedure was associated with high morbidity and mortality, as well as high rates of long-term pancreatic insufficiency for survivors.^{10,11} Overall, there has been a trend toward less invasive approaches to management of necrosis and infected necrosis with or without delayed surgical intervention, known as the “step-up” approach. Patients receive initial medical management with fluid resuscitation and antibiotic administration, followed by percutaneous catheters for drainage of infected fluid. The percutaneous catheters can be irrigated using large volumes of sterile saline and patients are monitored for improvement. Patients who fail to improve may be candidates for operative debridement. In general, postponement of operative debridement for as long as possible is encouraged, as it is associated with decreased morbidity and mortality; however, prolonged antibiotic treatment leads to increased infections with resistant organisms and fungi.¹⁹ Skilled endoscopists have also started to explore transgastric and transduodenal necrosectomy, although these methods are not yet standard of care.

Feeding Intolerance

It is well established that enteral nutrition, provided as early as possible, is beneficial to patients in the ICU. Malnutrition is associated with increased infections, reduced wound healing, increased mortality, prolonged hospital stay, and increased cost. Many critically ill patients present to the hospital with preexisting protein-calorie malnutrition, which is exacerbated by their acute illness. ICU admission leads to periods of starvation (nil per os for a variety of reasons), with simultaneous increased metabolic demand from the acute illness. Early enteral nutrition is encouraged and most studies support the dictum “if the gut works, use it.” The indications and methods for enteral feeding are discussed elsewhere in this text.

Studies have demonstrated that a substantial percentage of patients in the ICU develop intolerance to enteral feeding, which can be manifested by high gastric residuals, emesis, abdominal distension, or abdominal pain.²⁰ Most studies of critically ill patients report the ability to deliver only 40% to 60% of goal nutrients secondary to gastrointestinal dysmotility or other barriers to early nutrition.²¹ Once mechanical reasons for obstruction are ruled out, feeding intolerance in the critically ill patient stems from the presence of gastric dysmotility or ileus. Rapid resolution of dysmotility is crucial to allow progression of enteral feeding.

Gastric residual volumes are used as a surrogate marker for feeding intolerance, and thus “high gastric residuals” are frequently the rationale for interruption of feeding. Unfortunately, the relationship between gastric residual volumes and delayed gastric emptying is unclear, and the residual volumes that should trigger the cessation of enteral feeding are controversial.^{22,23} Some consensus groups agree that a gastric residual volume greater than 200 mL is abnormally high, but still recommend that this threshold should not trigger automatic cessation of enteral nutrition. Because there is no accepted definition for high gastric residuals, thresholds for holding enteral nutrition can vary among institutions, and caregivers at the same institution. Creation of an enteral tube feeding protocol that is not physician-dependent may also improve delivery of nutrients by minimizing feeding interruptions and standardizing the thresholds of residual volumes within an ICU.²⁴

Feeding intolerance in the critically ill patient can be attributable to the patient’s critical illness, medications, intra-abdominal pathology, or underlying disease. Feeding intolerance may also be due to ileus or bowel obstruction; mechanical obstruction must be ruled out prior to administering enteral nutrition aggressively. Gastric emptying is believed to be delayed in patients with traumatic brain injuries (TBIs) and elevated intracranial pressure (ICP); hyperglycemia may also contribute to delayed gastric emptying.²⁵ Endogenous or exogenous catecholamines are likely to decrease gastric emptying, whereas dopamine reduces antral contractions. Anticholinergics, calcium channel blockers, sedatives, and opiates, all of which are used commonly in the ICU, also slow gastric motility.

Therapeutic options for the treatment of delayed gastric emptying are imperfect. Prokinetic options are most widely used, but no regimen is perfect. Common prokinetic agents include metoclopramide or erythromycin as monotherapy, or in combination. Metoclopramide antagonizes the effect of dopamine on the gastric antrum and improves gastric motility when given as a 10 mg q6h, although the effect is blunted in TBI patients. With repeated administration, tachyphylaxis develops quickly and reliably such that after 7 days of routine metoclopramide administration, only 20% to 25% of patients continue to have successful nasogastric feeding.^{25,26} Another commonly utilized promotility agent, erythromycin, acts as a motilin agonist and can be given intravenously in doses of 1 to 3 mg/kg/d and likely has better prokinetic activity than metoclopramide. Unfortunately, patients also become resistant to the effects of erythromycin over time, such that after 7 days, only 30% to 45% of patients can be successfully fed via a nasogastric tube. Additionally, there are concerns that erythromycin can exacerbate antibiotic resistance or lead to cardiotoxicity. Cardiac toxicity can be minimized by using smaller doses; reportedly, an intravenous dose of 70 mg of erythromycin is as effective as a 200-mg dose in accelerating gastric emptying. Once feedings are tolerated, the prokinetic agent can be discontinued.

Combination therapy of metoclopramide plus erythromycin may be superior to the use of either drug alone and decreases the incidence of tachyphylaxis as first-line treatment of feeding intolerance or after the failure of monotherapy.²⁵⁻²⁷ Newer therapies with potential to improve gastric emptying include opioid antagonists such as methylnaltrexone or alvimopan. Methylnaltrexone and alvimopan theoretically do not cross the blood-brain barrier so that analgesia is maintained while the effects of opioids on the gastrointestinal tract are blunted. Both drugs have been tested in postoperative elective bowel resection patients and help accelerate recovery of bowel function or decrease postoperative ileus without increased pain. Unfortunately, these opioid antagonist agents have not been proved in the critically ill patient.²⁸ When drug treatment fails, alternatives can include parenteral nutrition or postpyloric feeding access. In fact, some clinicians advocate

enteral feeding into the small bowel as first-line enteral access. Controversy exists on the optimal anatomic location for feeding access, and this is discussed elsewhere in this text.

Other Enteral Feeding Issues: Hemodynamic Instability, Ileus, and Diarrhea

Patients in the ICU may undergo prolonged periods of starvation for reasons other than feeding intolerance, including imminent or recent surgical procedures, hemodynamic instability, diarrhea, and lack of functional enteral access. Some clinicians are reluctant to initiate early enteral feeding until the “acute” phase of the injury response has subsided, owing to the fear that immediate feeding will result in higher complications from delayed gastric emptying, such as aspiration of gastric contents. Despite this, large studies suggest that the benefits of early feeding outweigh the risks and the practice of early nutrition is becoming more common.

Giving enteral feeds on vasopressors continues to be contentious. Hemodynamic instability requiring vasopressors is often considered to be a relative contraindication to enteral feeding; however, the data supporting this are inconclusive. In healthy adults, enteral nutrition is associated with an increase in blood flow to the intestines. The concerns for feeding patients who are on vasopressors are 2-fold: Patients can develop intestinal ischemia from the increased demand when the circulatory system is not able to increase blood flow, or patients may experience a “steal” phenomenon, where blood is diverted to the splanchnic circulation leading to ischemia of other end organs. There have been a few case reports of very early enteral feeding being associated with intestinal ischemia in underresuscitated trauma patients but it is unclear whether the feeding or the inadequate resuscitation was the culprit leading to intestinal ischemia.²⁹ Whereas it is probably prudent to not feed patients in hemorrhagic shock or with rapidly escalating vasopressor requirements, some data suggest that enteral feeding is safe in patients receiving vasopressors.³⁰

Another common reason for delay of enteral nutrition is adynamic or paralytic ileus of the small bowel. Ileus can be caused by a number of

intra-abdominal and retroperitoneal processes, including intestinal ischemia, ruptured viscus, hemorrhage, pancreatitis, peritonitis, medications (opioids, anticholinergics), and electrolyte abnormalities. It may also occur after abdominal surgery. Ileus is heralded by abdominal pain, vomiting, and abdominal distension with obstipation and must be differentiated from a mechanical small bowel obstruction. Radiographic studies may help differentiate obstruction from ileus. Laboratory studies should be obtained, including a complete blood count, chemistries, and perhaps an arterial blood gas and lactate if there is concern for intestinal ischemia, although no laboratory test is definitive. Patients with worsening signs on serial abdominal examinations, or who develop a fluid requirement and acidosis, should have a surgical evaluation for obstruction or ischemia. Plain abdominal films performed at the bedside have limited value. On plain radiographs, ileus will show diffuse small bowel dilation (> 3 cm) with air-fluid levels and no distinct cutoff point. Air and stool present in the colon on a plain radiograph can be a reassuring sign that there is no mechanical obstruction present but is not particularly specific, as a patient with acute obstruction or a closed loop obstruction may not have had time to decompress the distal bowel. Patients who are suspected of having a mechanical obstruction should undergo a CT scan with oral and intravenous contrast. Nasogastric tube decompression can be used to ease symptoms of nausea and may help resolve the ileus.

Colonic pseudo-obstruction (Ogilvie syndrome) occurs typically in bedridden or elderly patients, but may also happen as a sequela of spinal cord injury, prolonged opioid use, or postoperatively from abdominal or nonabdominal surgery. It manifests characteristically with abdominal distension, abdominal pain, obstipation, and possibly tenderness; vomiting may or not be present. Plain radiographs demonstrate a dilated colon, usually most pronounced at the cecum, and should be performed as an initial diagnostic test to rule out a mechanical cause of obstruction such as volvulus. Perforation risk is approximately 3% but risk increases if the diameter of the cecum exceeds 12 cm or if the distension has been present for more than 6 days. Therapy should include correction of electrolyte abnormalities, cessation of narcotics, and nasogastric decompression. Neostigmine, 2 mg IV over a

period of 5 minutes, can be utilized to resolve the ileus. Administration of neostigmine should take place in the ICU, as some patients develop symptomatic bradycardia and require administration of atropine. A repeat dose of neostigmine may be administered after 3 hours.³¹ If neostigmine does not resolve the pseudo-obstruction (~ 15% of cases), colonoscopic decompression may be considered as success rates are high (~ 70%); complications include perforation, inability to decompress the colon, and recurrence. Surgical intervention may be necessary for patients who have perforated, patients who have had unsuccessful attempts at decompression, or patients with recurrent pseudo-obstruction after decompression.

Critically ill patients often develop diarrhea, defined as an increase in the fluidity, frequency, or quantity of bowel movements. The actual volume of stool that constitutes diarrhea is debated but typically is described as greater than 300 mL/d or greater than 4 loose stools per day. Diarrhea can lead to electrolyte imbalance, wound contamination, and dehydration, and may prompt providers to hold enteral nutrition, which can exacerbate malnutrition. Diarrhea may be attributable to one or multiple simultaneous causes, including enteral feeding formulas or regimens, malabsorption, underlying disease, medications, or infections.³² Medications that may cause diarrhea should be discontinued, such as metoclopramide, erythromycin, oral magnesium or phosphorus, or antibiotics. Diarrhea is the most commonly reported complication of enteral tube feeding; research on various feeding formula issues have been studied, including temperature, osmolality, fiber content and type, density, delivery rate, and formula content, but no factor in the feeding formula is consistently associated with development of diarrhea.³² Infectious diarrhea in the ICU can be secondary to *C. difficile*, *Klebsiella oxytoca*, *Clostridium perfringens*, *Salmonella* spp., *Staphylococcus aureus*, or gastrointestinal viruses.

For patients with profuse diarrhea, all possible offending medications should be discontinued and infectious sources should be treated. Several nutritional interventions have been studied, with limited success. Fiber-enriched formulas are supported by the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition in patients who have developed diarrhea,³³ but

not all clinical trials demonstrate an effect of fiber on diarrhea. Probiotics have been suggested as a way to recolonize the intestine and normalize the intestinal flora. However, the administration of probiotics is controversial in critically ill patients with abnormal immune responses; one study of patients with severe acute pancreatitis even showed increased mortality with probiotic prophylaxis.¹³ For patients with diarrhea that is deemed noninfectious, antidiarrheal agents may be considered but should be used with great caution. Opioid analogs may be considered; the most common form is diphenoxylate with atropine (1 tablet 3-4 times/d) or loperamide (up to 4 mg, 4 times/d).

Abdominal Compartment Syndrome

In the critically ill patient, pressure within the abdominal cavity can be increased pathologically above the patient's baseline. Prolonged elevations of intra-abdominal pressure can result in organ dysfunction and failure, known as ACS. In the healthy patient, physiologic intra-abdominal pressure is close to 0 mm Hg, although this can be increased chronically to 10 to 15 mm Hg in obesity or pregnancy. In the critically ill patient, pressures are generally increased to levels of 5 to 7 mm Hg.³⁴ Acidosis, multiple blood transfusions, sepsis, major trauma or burns, pancreatitis, ileus, liver dysfunction, and aggressive ventilator settings with high positive end expiratory pressures are factors that can further increase intra-abdominal pressure. IAH is defined as intra-abdominal pressure greater than 12 mm Hg. ACS is defined as intra-abdominal pressure greater than 20 mm Hg with evidence of end-organ dysfunction or failure.³⁴ Clinically, this may manifest with a tense, distended abdomen, progressive hypotension, oliguria, and increased airway pressures. Primary abdominal compartment syndrome is characterized by acute or subacute development of intra-abdominal hypertension in a relatively brief period of time secondary to pathology within the abdominopelvic cavity, usually due to abdominal trauma, ruptured abdominal aneurysm, hemoperitoneum, acute pancreatitis, acute peritonitis, or retroperitoneal hemorrhage. Secondary ACS is characterized by IAH that develops over a subacute or chronic time period as a result of an extra-abdominal cause such as sepsis, capillary leak syndrome, or aggressive fluid resuscitation following

a major burn. Patients may develop recurrent ACS after abdominal decompression, even with an open abdomen, if resuscitation is ongoing or dressings are too tight, or if abdominal closure was performed and intra-abdominal pressure becomes elevated again.

Intra-abdominal pressure monitoring is essential to the diagnosis of ACS. A variety of methods exist to measure pressure within the abdominal cavity, which include direct (via needle puncture into the abdominal cavity) or indirect (transduction of intra-abdominal pressure through a surrogate, such as the bladder or colon). Bladder pressure measurement has the most widespread adoption owing to the simplicity and minimal cost; additionally most critically ill patients already have a bladder catheter in place, so the measurement of pressure is relatively noninvasive. However, there is increased risk of urinary tract infection. Regardless of the technique utilized, several key principles need to be followed as outlined by the International Conference of Experts on Intra-abdominal Hypertension and Abdominal Compartment Syndrome in 2004.³⁴ Intra-abdominal pressure should be expressed in mm Hg and measured at the end of end expiration, with the transducer zeroed at the midaxillary line and ensuring that there are no abdominal muscle contractions. The reference standard is instillation of 25 mL sterile saline into the bladder; higher volumes of instilled fluid can overfill the bladder such that the transduced pressure becomes the pressure of the bladder wall instead of the intra-abdominal pressure. Changes in body position, and the presence of abdominal or bladder wall contractions have been demonstrated to impact the accuracy of intra-abdominal pressure measurements.³⁵

Treatment and management of ACS consists of 4 general principles: (1) serial monitoring of intra-abdominal pressures, (2) optimization of systemic perfusion and organ function in the presence of intra-abdominal hypertension, (3) institution of medical procedures to decrease intra-abdominal pressure and reduce end-organ dysfunction, and (4) prompt surgical decompression for refractory intra-abdominal hypertension or ACS. Generally, the “critical” intra-abdominal pressure at which end-organ dysfunction occurs differs among patients, but some trials have evaluated abdominal perfusion pressure (similar in concept to ICP monitoring and cerebral perfusion pressure), where the abdominal

perfusion pressure is equal to the mean arterial pressure minus the intra-abdominal pressure. Several retrospective trials have suggested that abdominal perfusion pressure above 50 to 60 mm Hg is associated with improved survival, but this has yet to be validated prospectively.³⁵

Several medical therapies have been hypothesized to temporize and treat mild IAH; however, if a patient is showing signs of end-organ damage, medical therapies are unlikely to have beneficial or expeditious enough effects to prevent the need for decompressive laparotomy. Pain, agitation, ventilator dyssynchrony, and use of accessory muscles during work of breathing all may contribute to increased intra-abdominal pressure. Patients at risk for ACS must be afforded adequate sedation and pain control. It has been suggested that neuromuscular blockade may allow for muscle relaxation to decrease the compliance of the abdominal wall, thus decreasing intra-abdominal pressure. However, the risks of pharmacologic paralysis must be weighed carefully against the uncertain benefits. Body positioning may also contribute to intra-abdominal pressure; elevation of the head of the bed and supine positioning may increase intra-abdominal pressure, but again the benefits of these positions in specific patient populations may outweigh the risk of supine and flat positioning. Other interventions that may theoretically decrease intra-abdominal pressure such as nasogastric and colonic decompression, diuretics, and renal replacement therapy have not been adequately studied in this patient population.

Surgical decompressive laparotomy is the standard treatment for patients who develop ACS. Once a patient’s IAH has become refractory to medical therapies, laparotomy is a lifesaving intervention. Surgical decompression results in an “open abdomen,” which is discussed further in the next section. Decompressive laparotomy is also a reasonable therapeutic option in a patient with intra-abdominal hypertension for whom the risk of ACS is high but the patient has not yet manifested end-organ damage.³⁵

The Long-Term Open Abdomen

Use of damage control surgery with temporary abdominal closure has gained popularity since the late 1980s as a way to salvage critically ill trauma patients with physiologic compromise due to massive

hemorrhage in the abdomen. This approach has been adapted for use in other nontrauma surgical patients with abdominal catastrophes, such as ACS or pancreatic necrosectomy with expected serial debridement procedures. There are generally 3 stages to damage control surgery: abbreviated surgery, resuscitation, and delayed definitive closure. The initial surgery is abbreviated to allow for rapid control of hemorrhage or abdominal contamination, and may require packing for hemostasis. At this point, the abdominal contents are covered with a temporary dressing. This is followed by resuscitation, warming, and correction of any existing coagulopathy in order to allow the patient to have normalization of physiology. Implicit in this approach is the planned surgical reexploration, which typically occurs 12 to 72 hours after the index operation. Aggressive resuscitation between the first and second operation may render the abdomen unable to be closed and serial dressing changes and staged operations may be necessary to obtain closure or coverage of the abdominal contents. Ideally, patients should undergo definitive fascial closure whenever possible, even if closure must be performed in stages; in some cases, closure is impossible. Surgical options for these patients are limited and unappealing but include temporary mesh closure, skin-only closure, or split-thickness skin grafts with planned ventral hernia. Many of these patients develop severe loss of domain and loss of function of the abdominal wall, eventually necessitating extensive reconstructive surgery to regain some abdominal wall functionality.

All patients who undergo damage control surgery with an open abdomen are at high risk for infectious complications. Surgical site infections have been reported to occur in as many as 83% of cases, and postoperative fascial dehiscence is reported in up to 25% of patients who have had an open abdomen.³⁶ However, no data support antibiotic prophylaxis of the open abdomen. Particularly concerning in patients who are unable to undergo fascial closure is the development of bowel fistulae. The incidence of fistulae in patients with an open abdomen is approximately 5% to 19%, and varies according to the initial indication for damage control surgery.³⁷ Of unique concern in this patient population is the “enteroatmospheric” fistula, which occurs because there is no tissue that overlies the

exposed bowel and spontaneous healing becomes impossible. Patients with enteroatmospheric fistulae should have radiologic evaluation with enteral contrast to clarify the location of the fistula (proximal or distal bowel) to create strategies for enteral nutrition, if possible, and minimize fluid and electrolyte losses. Continuous leakage of enteric contents into the wound contributes to elevated catabolism, protein loss, infection/sepsis, and increased mortality. These patients likely require serial abdominal operations to control enteric leakage and reestablish bowel continuity.

CONCLUSIONS

Critically ill patients are susceptible to a variety of sources of abdominal dysfunction. These issues must be diagnosed quickly and addressed in a way that considers each patient’s current clinical status and concurrent critical issues.

Gastrointestinal Hemorrhage (Upper and Lower)

Pari Shah, MD, MSCE

Gastrointestinal (GI) bleeding accounts for a significant number of hospitalizations every year with a median length of stay of 4 days and with greater than 30% of patients requiring intensive care unit (ICU) care.¹ Early diagnosis of the cause and appropriate

intervention can significantly reduce ICU and hospital stays and improve morbidity and mortality. This chapter focuses on a discussion of the differential diagnosis of upper and lower GI bleeding and management principles.

Upper GI Bleeding

KEY POINTS

- 1 The first step in the management of upper GI bleeding (UGIB) is to assess hemodynamic status and resuscitate if there is any instability. Restricted transfusion strategies (transfusion for hemoglobin [Hb] < 7) yield better outcomes than aggressive transfusion strategies.
- 2 Patients should be stratified for risk of rebleeding and mortality based on clinical predictors and endoscopic findings.
- 3 Early endoscopy (within 24 hours) for UGIB improves outcomes and length of hospital stay; endoscopic treatment is warranted for high-risk lesions (active bleeding vessel, oozing vessel, visible vessel). Angiography with embolization or surgery can be used as rescue therapy for patients who fail endoscopic therapy.
- 4 Patients with acute hemorrhage suspected from varices should undergo early endoscopy and endoscopic band ligation for treatment of varices that have stigmata of bleeding; transjugular intrahepatic portosystemic shunting (TIPS) can be used as rescue therapy for patients who fail endoscopic therapy.
- 5 Pharmacologic therapy in conjunction with endoscopic therapy can improve rebleeding rates and survival.

INTRODUCTION

UGIB has an incidence of 48 to 160 cases/100,000 adults per year.² Bleeding from an upper GI source is defined by overt presentation of bleeding represented as melena, hematemesis, or occasionally

hematochezia, with localization of the bleeding lesion to the esophagus, stomach, or duodenum. UGIB is 5 to 6 times more common than lower GI bleeding (LGIB). The clinical presentation of UGIB can vary widely from clinically insignificant bleeding

to life-threatening bleeding. Mortality from UGIB is generally between 10% and 14%.³ The management principles of UGIB focus on the risk stratification of patients and the early diagnosis and treatment of underlying causes.

HISTORY

UGIB is generally described as the presentation of melena, black tarry stools, or the description of hematemesis, vomiting of blood. The presentation may be insidious in onset or abrupt. Details obtained on history will suggest the duration of the bleeding and whether it is acute or chronic. Patients will often describe the presence of diarrhea associated with UGIB because blood passing through the GI tract often results in multiple loose bowel movements. Rapid UGIB may present as hematochezia (bright red blood or maroon stools from below) in addition to melena. Approximately 10% of patients with hematochezia may have upper GI sources of their bleeding.

Symptoms that accompany UGIB may reflect significant hemodynamic compromise; these include dizziness, light-headedness, chest pain, shortness of breath or dyspnea on exertion, weakness, or fatigue. Symptoms such as chest pain or shortness of breath suggest a more acute hemodynamic compromise and clinically significant blood loss. Patients without accompanying hemodynamic symptoms suggest a slow bleeding rate or a more chronic process. Symptoms such as abdominal pain, abdominal cramping, or postprandial pain may be helpful in narrowing the differential diagnosis of the source of the bleeding.

Essential to the history taking is obtaining information of comorbid conditions the patient may have and any medications the patient may be taking. Comorbid conditions can help in diagnosis, for example, liver disease may suggest a possible diagnosis of varices. Comorbid conditions are also important in treatment; for example underlying cardiac or pulmonary disease may be significant to the management of the patient. Medications that may play a role in UGIB include nonsteroidal anti-inflammatory drugs (NSAIDs), or antithrombotic agents, such as antiplatelet medication or anticoagulants. NSAIDs may cause UGIB through the formation of peptic ulcers, while therapy with

antithrombotic agents may exacerbate UGIB from underlying lesions. A recent meta-analysis evaluated 35 randomized controlled trials (RCTs) and demonstrated that antiplatelet therapy with aspirin (ASA) (defined as 75-325 mg/d) increased the risk of UGIB 1.5 times compared to nonusers. The odds ratio (OR) of UGIB in patients taking ASA and clopidogrel was 1.86 when compared to ASA alone and the OR of GI bleeding with anticoagulants was 1.93 when compared to ASA alone.⁴ New anticoagulants, such as thrombin and factor Xa inhibitors, have also been shown to increase risk of GI bleeding; a meta-analysis analyzing 43 RCTs revealed an overall OR of GI bleeding of 1.45 when compared to traditional anticoagulants and an OR as high as 5 when used in the setting of acute coronary syndrome.⁵ Information about the dose, duration, and effects of these medications can help direct further care.

PHYSICAL EXAMINATION AND INITIAL ASSESSMENT

The physical examination focuses initially on hemodynamic evaluation. Assessing a patient's volume status with blood pressure monitoring and heart rate (HR) evaluation is crucial to determining the critical nature of the GI bleed. Patients with hemodynamic instability, suggested by HR greater than 100 beats/min, systolic blood pressure (SBP) less than 100 mm Hg, or the presence of orthostatic hypotension (defined by drop in SBP of > 20 mm Hg or rise in HR of > 20 beats/min from lying to sitting or sitting to standing) or the presence of syncope suggest a loss of blood volume of greater than 10% and indicates an urgency for volume resuscitation.

Other aspects of initial examination include assessment of the abdomen and rectum. Abdominal auscultation and palpation may help to narrow down the differential diagnosis. Patients with physical examination findings of peritonitis or clinical concern for perforation should be triaged for computed tomographic (CT) scan prior to further workup. Rectal examination is essential to confirm the presence of melena and support the etiology of UGIB and to help distinguish UGIB from lower gastrointestinal bleeding (LGIB). Patients in whom UGIB needs to be further confirmed and in whom

endoscopy is being considered may benefit from nasogastric (NG) tube placement and gastric lavage. NG lavage provides supporting information of UGIB by witnessing the return of bright red blood or coffee ground material. It allows for the determination of ongoing UGIB: bright red blood that does not clear with lavage suggests active UGIB while clearance of red blood and return of coffee ground material suggest recent UGIB that may have stopped. Finally, NG lavage may allow for clearance of gastric contents facilitating views of the stomach on upper endoscopy. Some physicians advocate for NG lavage in all patients suspected of UGIB; in our practice, we determine its role in diagnosis and management on a case-by-case basis.

Laboratory studies supplement the assessment made on initial physical examination. The patient's Hb should be assessed immediately with a complete blood count (CBC) and compared to previous Hb levels to assess change; however the Hb level can be misleading in acute UGIB if there has not been sufficient time for the cardiovascular system to equilibrate

and reflect the blood loss. Other laboratory values that may assist in the assessment are the blood urea nitrogen (BUN) and creatinine, the ratio of which can often be greater than 20:1 in patients with UGIB. All patients with evidence of GI bleeding should have a type-and-cross match sent to establish blood type given the possible need for blood transfusion.

Initial Management

The goals of initial management focus on resuscitation. Additionally, management decisions must be made to minimize ongoing bleeding and to minimize the impact of the UGIB on other organ systems (Figure 36–1).

Resuscitation is initiated and driven by amount of blood loss as assessed on CBC and by hemodynamic compromise. All patients should have 2 large-bore peripheral venous access catheters or a central venous access placed. Patients with altered mental status or respiratory compromise should be intubated for airway protection. Patients with significant hemodynamic compromise should be admitted to

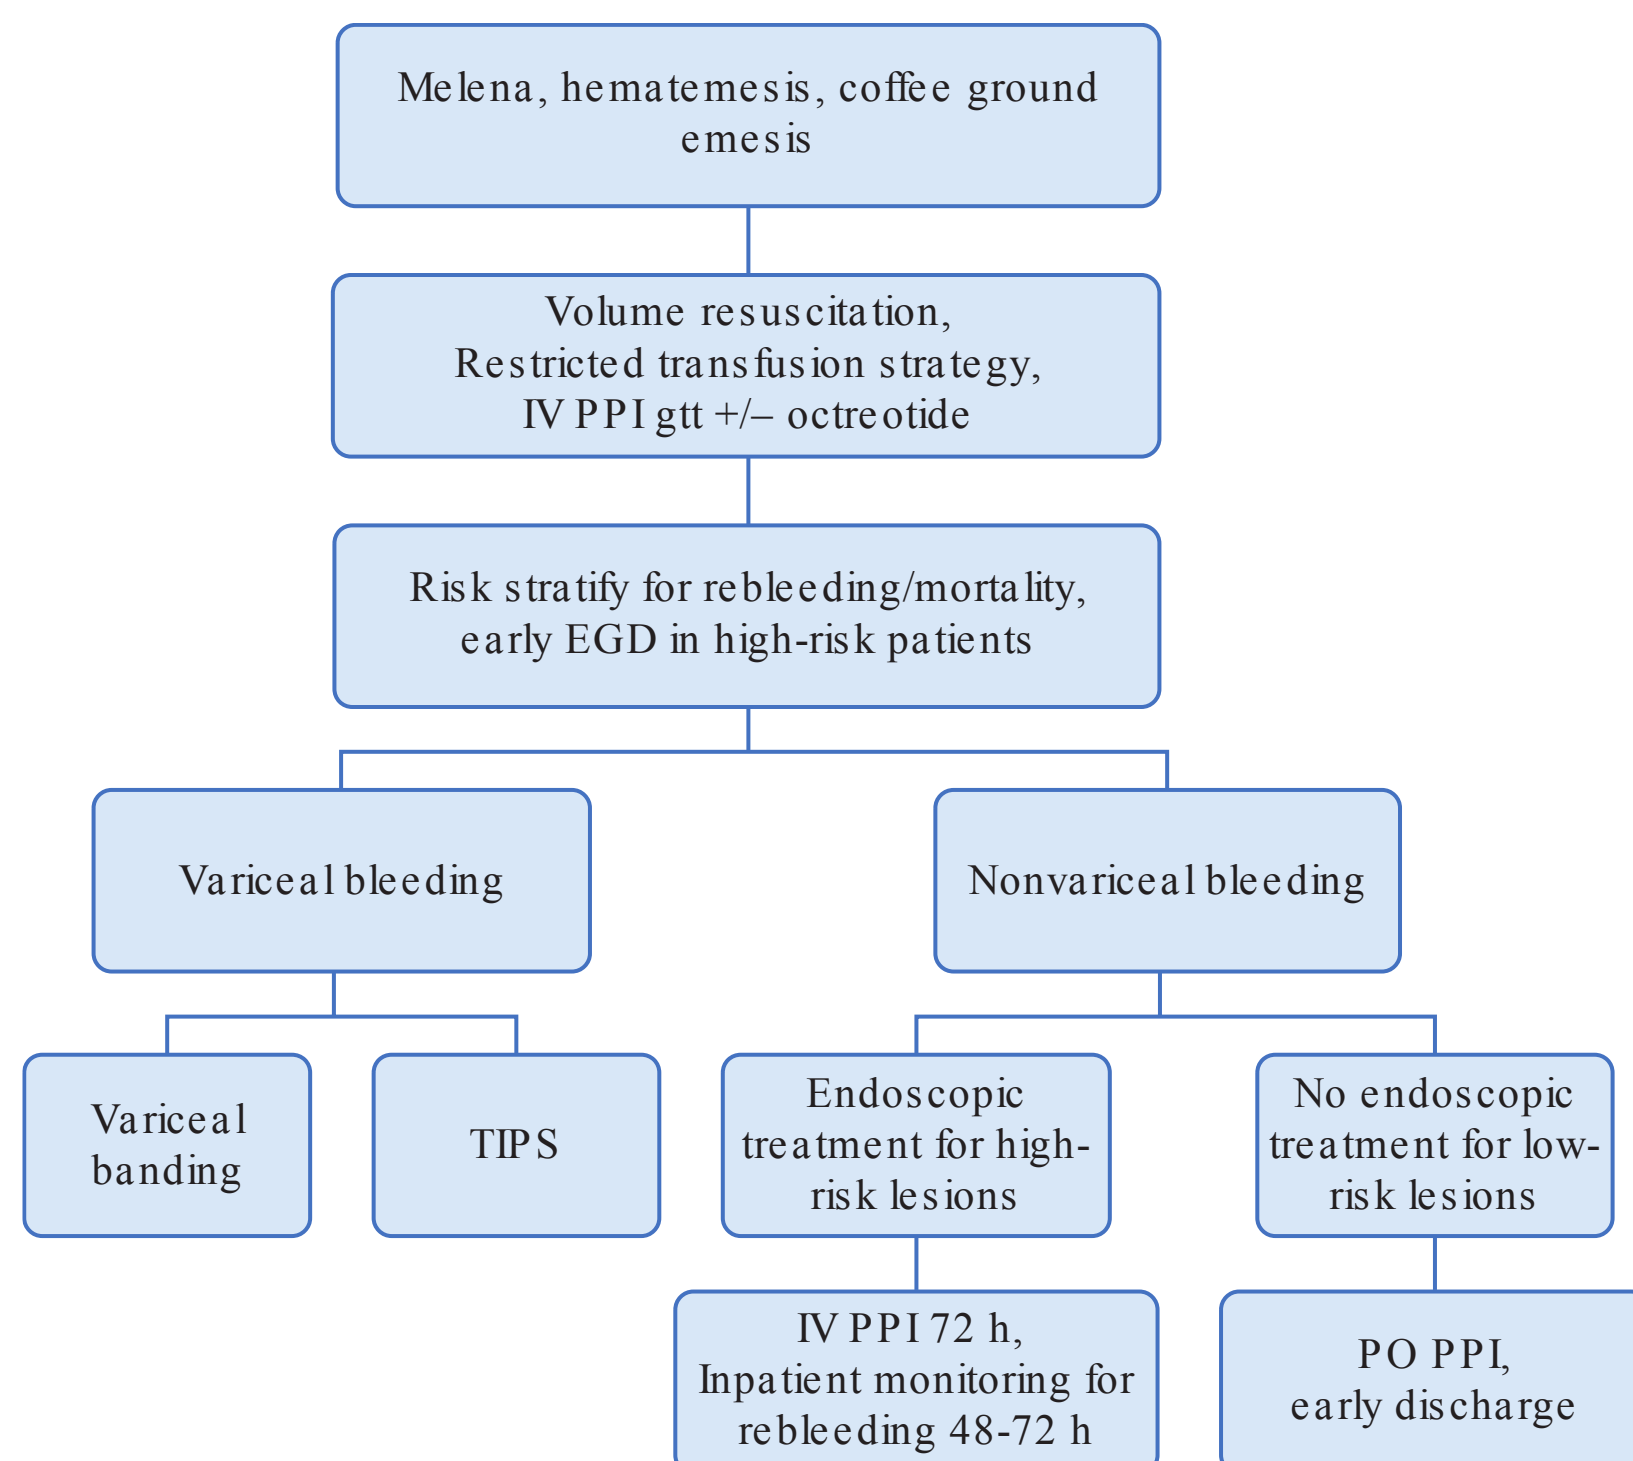

FIGURE 36–1 Management of UGIB.

the ICU for close monitoring and management. Volume replacement should be initiated immediately with normal saline or lactated Ringer solution. Colloid solutions can be given.

The goal of blood transfusion is to increase the delivery of oxygen to the tissues. The need for blood transfusion is based on initial Hb and assessment of whether UGIB is ongoing and significant. Patients with massive UGIB may benefit from an aggressive transfusion strategy; patients with clinically stable UGIB and low-risk or intermediate-risk UGIB are more likely to benefit from a restrictive transfusion strategy. A recent RCT of patients with acute UGIB comparing a restrictive transfusion strategy (transfusion for Hb < 7) versus a liberal transfusion strategy (transfusion for Hb < 9) found that patients with a restrictive transfusion strategy had higher probability of survival at 6 weeks, decreased rates of rebleeding, and lower number of adverse events. This benefit is most clearly understood in patients with cirrhosis and portal hypertension-related variceal bleeding.⁶ Aggressive reconstitution of blood volume has previously been shown to induce rebound increases in portal pressure, which may precipitate rebleeding of varices; a restrictive transfusion strategy was shown to be beneficial in these patients. Additionally, a restrictive transfusion strategy was shown to be beneficial in patients with nonvariceal UGIB, which may be due to decreased transfusion-related complications, decreased transfusion-related abnormalities in coagulation, or decreased cardiac complications such as pulmonary edema.⁶ Patients should be evaluated on a case-by-case basis for transfusion needs, taking into consideration age, coexisting comorbidities, and hemodynamic status; however, a restrictive transfusion strategy is favored.

Patients should concurrently have prothrombin time (PT) and activated partial thromboplastin time (aPTT) levels checked and corrected as necessary. In patients with ongoing GI bleeding, the goal international normalized ratio (INR) is less than 1.5 and fresh frozen plasma (FFP) can be given to achieve this in the short term. Patients who are hemodynamically stable can proceed to upper endoscopy while transfusion is being given. A recent study demonstrated no difference in risk of rebleeding following endoscopic therapy in patients with

mild-to-moderate elevated INR compared to normal INR.⁷ Patients with history of thrombocytopenia should have platelet levels checked and corrected to values greater than 50,000/mm³.

After the initial management, the focus is on minimizing ongoing UGIB. UGIB is often divided between nonvariceal bleeding and variceal bleeding and initial assessment for chronic liver disease helps to differentiate these possibilities. The most common cause of nonvariceal UGIB is peptic ulcer disease (PUD). Thus, to reduce ongoing bleeding from this potential cause, all patients are recommended to receive intravenous (IV) proton pump inhibitor (PPI) therapy until further risk stratification is completed. This is generally given in the form of intravenous pantoprazole starting with a bolus of 80 mg followed by a continuous infusion of 8 mg/h. A RCT of patients receiving PPI infusion versus placebo prior to endoscopy revealed lower need for endoscopic intervention and decreased length of hospital stay in patients treated with pre-endoscopic PPI.⁸ PPI therapy is thought to stabilize blood clot and reduce risk of bleeding by decreasing levels of gastric acid, which can inhibit platelet aggregation and lead to clot lysis.⁹

Patients in whom chronic liver disease is suspected and who have a risk of variceal bleeding are recommended to receive pharmacologic therapy in conjunction with endoscopic therapy as well. Somatostatin and somatostatin analogues such as octreotide and vapreotide have been evaluated in the pre-endoscopic period for patients in whom variceal bleeding is suspected. Octreotide is the only medication of this class currently available in the United States; intravenous octreotide infusion starting with 50 µg bolus followed by 50 µg/h continuous infusion is recommended to be given in all patients in whom variceal bleeding is suspected followed by early endoscopy. A meta-analysis of 8 randomized trials revealed improved endoscopic control of initial bleeding in patients who received pharmacologic therapy in addition to endoscopic therapy.¹⁰ Terlipressin, a synthetic analogue of vasopressin, has also been evaluated and been shown to be effective in acute variceal bleeding; however, this medication is not yet available in the United States. A recent study comparing somatostatin, octreotide, and terlipressin in a randomized fashion showed no

difference in the hemostatic effects or safety between these medications.¹¹

Additionally, patients with cirrhosis and suspected UGIB are recommended to receive short-term prophylactic antibiotics. Prophylactic antibiotics are intended to decrease the risk of bacterial infection such as spontaneous bacterial peritonitis and other infections; studies evaluating the role of prophylactic antibiotics have shown decreased rates of infection and improved survival.¹² Norfloxacin 400 mg twice daily given orally for 7 days is the recommended antibiotic, though other fluoroquinolones have also been shown to be effective. Additionally, IV ceftriaxone 1 g/d has been studied and shown to be effective.

RISK STRATIFICATION

An estimated 80% of patients with UGIB will spontaneously stop without intervention other than those described earlier. Patients who have completed initial resuscitation should be evaluated for evidence of ongoing bleeding, risk of rebleeding, and risk of mortality. This assessment should be made first based on clinical and laboratory findings, and then may be modified after endoscopic findings. Several scoring systems have been developed to stratify patients into high risk or low risk for rebleeding and mortality (Table 36–1). In previous studies, clinical predictors of rebleeding and mortality include age greater than 65, shock, comorbid

TABLE 36–1 Rockall score.

Variable	Age	Shock	Comorbidity	Diagnosis	Evidence of Bleeding
0 point	< 60	No shock	None		None
1 point	60-79	Pulse > 100 SBP > 100		MWT	
2 points	> 80	SBP < 100	CHF CAD Other	All other diseases	Blood Adherent clot Spurting vessel
3 points			ARF Liver disease Metastatic cancer		

Score < 3 points—good prognosis; score > 8—poor prognosis.
ARF, acute renal failure; CAD, coronary artery disease; CHF, congestive heart failure; MWT, Mallory-Weiss tear; SBP, systolic blood pressure.

Glasgow-blatchford score

Variable	Blood Urea	Hb—Men (g/L)	Hb—Women (g/L)	SBP (mm Hg)	Pulse (Beats/min)	Presentation	Comorbidity
0 point							
1 point		≥ 12, < 13	≥ 10, < 12	100-109	≥ 100	Melena	
2 points	≥ 6.5, < 8			90-99		Syncope	Liver disease CHF
3 points	≥ 8, < 10	≥ 10, < 12		< 90			
4 points	≥ 10, < 25						
5 points							
6 points	≥ 25	< 10	< 10				

illnesses, and clinically significant UGIB as evidenced by hematemesis, hematochezia, or melena; low initial Hb or high transfusion requirements; and hemodynamic instability or syncope. Additionally, sepsis, elevated urea, creatinine, or serum aminotransferase levels have been predictors of poor clinical outcome.^{2,3} Two scoring systems commonly used to risk-stratify patients are the Blatchford score and the Rockall score, which can be initially calculated on clinical and laboratory data and updated based on endoscopic findings. Patients considered high risk should undergo upper endoscopy immediately after resuscitation is complete and the patient is clinically stable to undergo a procedure. These patients often require ICU stay, either for monitoring or to facilitate bedside endoscopy. If patients demonstrate evidence of active UGIB, we will often recommend intubation in the ICU for airway protection. Prior to endoscopy, it is often helpful to consider use of a promotility agent such as metoclopramide or erythromycin to facilitate clearance of the stomach and improve endoscopic visualization. Patients should be monitored closely in the interval between presentation and endoscopy with every 6- to 8-hour CBC depending on the clinical presentation.

For nonvariceal UGIB, endoscopic features can also be used to predict risk of rebleeding and mortality. The presence of high-risk stigmata as defined by the Forrest classification has been associated with higher rates of rebleeding and mortality. High-risk stigmata include actively bleeding vessel (Forest class IA), oozing blood (IB), and nonbleeding visible vessel (IIA). Adherent clot (IIB) is felt to be moderate risk. Flat pigmented spots (IIC) and clean-based ulcers (III) are low-risk lesions for rebleeding. The complete Rockwell score (see Table 36–1) can be used when clinical criteria and endoscopic criteria are available to determine risk of rebleeding and mortality.

Varices are present in approximately 50% of patients with cirrhosis and their presence correlates with severity of liver disease. Variceal hemorrhage occurs at a rate of 5% to 15% per year; predictors of variceal hemorrhage include size of varices, decompensated cirrhosis (Child-Pugh class B/C), and the endoscopic presence of red wale signs at the time of screening endoscopy (citation). Patients who have variceal bleeding have a median rebleeding rate of

63% within 1 to 2 years and mortality of at least 20% at 6 weeks.¹³ Predictors of rebleeding and mortality include Child-Pugh class, Model for End-Stage Liver Disease (MELD) score, renal failure, bacterial infection, hypovolemic shock, active bleeding at endoscopy, hepatocellular carcinoma, and hepatic venous pressure gradients (HPVGs) of greater than 20 mm Hg when measured within 24 hours of variceal bleed. A recent study described a MELD-based model to predict risk of mortality among patients with acute variceal bleeding and was demonstrated to be more accurate than other proposed prediction models.¹⁴

DIFFERENTIAL DIAGNOSIS

The most common causes of UGIB remain similar over time; a recent study reviewing the most common causes of UGIB at a large urban hospital cited PUD as the diagnosis in 34% of cases followed by variceal bleeding in 33% of cases.¹ Ninety percent of all PUD is caused by either infection with the gram-negative bacterium *Helicobacter pylori* or by the use of NSAIDs. *H. pylori* is found in as many as 90% of patients with duodenal ulcers and 70% of patients with gastric ulcers. The bacteria are transmitted via the fecal-oral route and are most commonly acquired in childhood. Most infected individuals are asymptomatic with no clinical consequence; a subset of patients can develop decreased mucosal barriers and increased mucosal susceptibility to gastric acid damage. Patients with persistent infection and chronic inflammatory changes can develop ulcers.

NSAIDs are a widespread and commonly used class of medications. Chronic use with even low-dose aspirin for cardioprotective measures can lead to mucosal changes throughout the GI system with ulcerations in the stomach, duodenum, and even the distal small bowel and colon. NSAIDs result in prostaglandin inhibition with subsequent decreased mucosal barriers and increased mucosal susceptibility to gastric acid injury. In addition, NSAIDs can cause direct mucosal injury resulting in erosions and ulcerations. PUD can also be seen in patients with severe stress, trauma, burns, sepsis, and prolonged ICU stays.

Variceal formation is caused by collateral vessels in the GI tract as a consequence of portal

hypertension in patients with chronic liver disease. The most common site of varices is the esophagus though varices can also form in the gastric fundus and cardia. Portal hypertension can cause other gastric changes in the form of portal hypertensive gastropathy, a diffuse mucosal change in the stomach. Variceal bleeding can present as acute-onset severe UGIB with associated hemodynamic compromise. The decrease in portal pressures by bleeding can lead to self-resolution; however, the risk of rebleeding remains high and can be exacerbated by aggressive volume resuscitation, as described earlier.

Other causes of UGIB include vascular malformations such as arteriovenous malformations (AVMs) or Dieulafoy lesions, traumatic lesions such as Mallory-Weiss tears of the esophagus, or malignant lesions such as gastric cancer or esophageal cancer.

FURTHER MANAGEMENT

Endoscopic therapy, in combination with pharmacologic therapy, is the main tool used for diagnosis and treatment of UGIB. Early endoscopy, defined by esophagogastroduodenoscopy (EGD) within the first 24 hours after presentation, to localize the site of bleeding and treat bleeding lesions has been shown to improve outcomes and reduce lengths of hospitalization. Most endoscopic findings can be treated within the same setting to stop active bleeding and reduce risks of rebleeding.

Nonvariceal UGIB

In patients with nonvariceal UGIB, high-risk stigmata, such as actively bleeding vessel, oozing vessel, or nonbleeding visible vessel, should be treated endoscopically. It is unclear whether treatment of adherent clot is beneficial; generally accepted practice is to attempt to gently dislodge the clot and treat the lesion based on appearance underneath. Low-risk lesions, such as pigmented spots or clean-based ulcers, do not require endoscopic treatment.

Endoscopic treatment consists of one or more techniques to attempt to stop active bleeding and prevent rebleeding. Tools available to the endoscopist include injection of epinephrine at a concentration of 1:10,000, thermocoagulation of the lesion with bipolar electrocautery probe, or placement of clips. A recent meta-analysis suggested that injection

therapy is better than no therapy but that combined therapy (injection plus thermocoagulation or injection plus clips) is better than monotherapy with injection alone. Monotherapy with thermocoagulation or clips is equivalent in efficacy to combined modality therapy.¹⁵ Routine second look endoscopy is not recommended and should be considered on a case-by-case basis. Evidence of rebleeding or inability to identify the bleeding lesion on initial endoscopy is generally considered indication for second endoscopy.

Patients with bleeding that cannot be localized on endoscopic evaluation or patients who have ongoing bleeding despite endoscopic therapy should be considered for surgery or for interventional radiology directed angiography and percutaneous embolization.

Patients with low-risk clinical features and low-risk endoscopic features may be discharged home after endoscopy; RCTs of this highly select group of patients suggest no difference in outcomes with a policy of early discharge versus inpatient observation. These patients need to have close outpatient monitoring and follow-up.

All patients should be discharged with oral PPI therapy to decrease risk of rebleeding with dosage and duration determined by etiology of bleeding; most patients are given once-daily PPI therapy for 8 weeks with close outpatient follow-up. Patients with PUD should be evaluated for *H pylori* with treatment of any positive results to minimize risk of recurrent ulcers and facilitate ulcer healing. These patients should have eradication confirmed 2 weeks after completion of their PPI therapy. Patients with NSAID use should discontinue use if possible. Patients who require low-dose ASA for cardiovascular protection should resume therapy when the risk of cardiovascular complications outweighs the risk of rebleeding; this appears to occur as early as 5 days after the onset of bleeding and decisions about timing of ASA resumption should be made with a multidisciplinary approach. Patients who require ASA and clopidogrel who have UGIB should continue on PPI therapy. The role of PPI therapy in combination with ASA and clopidogrel was evaluated in a RCT (COGENT trial), which examined the risk of adverse GI events and adverse cardiovascular events in patients taking ASA and clopidogrel randomized

to PPI use or placebo. This study found a statistically significant reduction in adverse GI events in patients taking once-daily omeprazole with no difference in cardiovascular events between the 2 groups.¹⁶ This study supports the benefit of PPI use in prevention of primary GI events. The benefit of PPI in preventing rebleeding is also likely to outweigh the hypothesized increase in risk of cardiovascular events attributable to the interaction between PPI therapy and clopidogrel. Recent guidelines on antiplatelet therapy management have been changed to reflect this consensus.

Variceal UGIB

Early endoscopy and endoscopic intervention has also been shown to improve outcomes in patients with variceal bleed. Variceal bleeding is identified when active bleeding is seen from a varix, when a “white nipple” is seen overlying the varix, when clots are seen overlying a varix, or when varices are seen with no other source of UGIB identified. Varices are described as number of columns and are graded into categories of small or large based on their appearance. Endoscopic interventions available for the treatment of variceal bleeding includes endoscopic variceal ligation (EVL) with the use of rubber bands placed at the base of the varix or use of sclerotherapy with injection of agents such as N-butyl-cyanoacrylate or isobutyl-2-cyanoacrylate. Endoscopic therapy in conjunction with pharmacologic therapy is the treatment of choice for bleeding varices; in general, endoscopic treatment with EVL is the preferred form of treatment by consensus. Sclerotherapy is recommended if EVL is not technically feasible.

Patients who fail endoscopic therapy or patients in whom early rebleeding occurs should be evaluated for shunt therapy, either through transjugular intrahepatic portosystemic shunt (TIPS) placement or through surgical shunt placement. One recent study demonstrated survival benefit with early TIPS placement (within 24 hours of bleeding) in patients with acute variceal bleeding and HVPG greater than 20 mm Hg.¹⁷ Patients who undergo shunt placement experience higher rates of hepatic encephalopathy; thus, while TIPS is felt to be equally effective in treatment of variceal bleeding with no difference in overall survival, it is recommended as a rescue therapy

in patients who have failed EVL and pharmacologic therapy because of this significant side effect. Balloon tamponade via placement of a Blakemore or Minnesota tube may be used to temporarily control bleeding prior to definitive therapy in patients with acute variceal bleeding; this is generally only recommended in patients with massive variceal bleeding as part of temporizing measures until definitive therapy with endoscopy or TIPS is available.

Patients who survive an episode of acute variceal hemorrhage are at high risk of rebleeding and death. Thus it is important that patients be treated to minimize risk of recurrence. Patients who undergo EVL should be started on a nonselective beta-blocker as soon as they have remained 24 hours without evidence of rebleeding to reduce portal pressures. Patients who have EVL are recommended to undergo repeat EGD at 7- to 14-day intervals until complete obliteration of varices is seen, usually requiring between 2 and 4 sessions. Combination of endoscopic therapy plus pharmacologic therapy with nonselective beta-blocker has been shown to be more effective than EVL alone with decreased rebleeding rates in 2 RCTs. Patients who undergo TIPS for treatment of variceal bleeding do not require any further therapy. All patients with clinically significant variceal bleeding should be referred for liver transplant evaluation if they are appropriate candidates.¹⁸

CONCLUSIONS

UGIB should be confirmed quickly by clinical examination with identification of melena or evidence of hematemesis or evidence of positive NG lavage. The patient's hemodynamic status should be assessed and resuscitation initiated rapidly to correct abnormalities. Empiric therapy with intravenous PPI and/or intravenous octreotide can help to reduce active bleeding and/or stabilize clot. Early endoscopic evaluation and therapy of high-risk lesions improve outcomes and reduces length of hospital stay. Patients should be managed endoscopically if high-risk lesions are identified. Patients should be monitored after intervention for rebleeding with continued adjuvant pharmacologic therapy (PPI, octreotide, nonselective beta-blockers, antibiotics) as indicated to decrease rates of rebleeding and mortality.

Lower GI Bleeding

KEY POINTS

- 1 Patients with hematochezia and clinical instability should be evaluated for possible UGI source of bleeding.
- 2 Diverticulosis is the most common etiology of LGIB; localization can be difficult and is often a diagnosis of exclusion.
- 3 Colonoscopy is the first step in localization of etiology of LGIB in patients with hematochezia and clinical stability.
- 4 Patients with clinical instability or recurrent LGIB should be evaluated by CT angiogram and consideration of interventional radiology (IR)-directed embolization if a source is identified. Surgery can be considered in refractory patients.

INTRODUCTION

LGIB is defined as bleeding from a lesion distal to the ligament of Treitz. The most common site of LGIB is the colon; bleeding from the small intestine is much less common. LGIB generally presents clinically as hematochezia or bright red blood from the rectum. LGIB can present in an acute manner or a subacute manner and is managed with many of the same principles used to manage UGIB.

HISTORY

As described, most patients with LGIB will describe the presentation of hematochezia that occurs acutely or subacutely. Hematochezia can present as large quantity or small quantity, can be described in isolation or to be mixed in with brown stool. Patients may have associated symptoms that can help narrow the differential diagnosis such as symptoms of diarrhea, abdominal pain, or tenesmus. Eliciting past medical history and medication use is as important in LGIB as it is in UGIB and may help to narrow the differential diagnosis. Understanding and managing comorbid conditions are similar to that in patients with UGIB and patients should be evaluated for the presence of underlying cardiac or pulmonary diseases.

PHYSICAL EXAMINATION AND INITIAL MANAGEMENT

Similar to UGIB, patients' initial evaluation includes evaluation of vital signs and clinical status. This involves evaluation of heart rate, blood pressure, and orthostatic measurements. Assessing the volume status and proceeding with resuscitation are similar as in patients with UGIB. Patients should have 2 large-bore IVs placed, followed by infusion of crystalloid, colloids, and blood to correct the volume status. Patients with severe volume loss and clinical consequences should be admitted to the ICU for closer monitoring and management. Patients with clinically significant hematochezia should be evaluated for the possibility of UGIB; approximately 10% of patients with UGIB will present with hematochezia. These patients should be evaluated with NG lavage for risk stratification and may require EGD prior to any additional workup to rule out UGIB causes.

Patients who are clinically stable can be further evaluated based on clinical presentation. As with UGIB, checking serum Hb further differentiates the clinical impact of bleeding. Restrictive transfusion strategies are recommended in patients with low or intermediate risk. Additional laboratory studies

such as lactic acid may assist in narrowing the differential diagnosis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of overt LGIB is broad. Diverticular bleeding is the most common cause of LGIB and accounts for 40% of all LGIB.¹⁹ Diverticulosis increases with age and the overall prevalence is estimated to be 30% to 50% with as many as 60% of people over 80 years being affected. The incidence of bleeding is estimated to be 5% to 50% in patients with diverticulosis. The clinical presentation of diverticular bleeding is generally consistent with arterial bleeding. Patients may have acute onset of painless hematochezia that ceases spontaneously in most cases with recurrent bleeding in 14% to 38% of cases. Diverticular bleeding can come from either the left colon or the right colon and localization of the site of bleeding can often be challenging. Because most cases resolve spontaneously without rebleeding, diagnosis is often made after exclusion of other potential causes of bleeding.

Ischemic colitis accounts for 1% to 19% of LGIB. This results from sudden loss of blood flow to the mesenteric vessels and most commonly affects the areas of the colon described as “watershed” areas: the splenic flexure and the rectosigmoid junction. Ischemic colitis may occur as a result of an embolic or a thrombotic event or because of transient hypoperfusion or vasospasm of the mesenteric vessels. Patients generally describe sudden onset of abdominal pain accompanied by hematochezia and may have advanced age, or significant cardiovascular disease. Ischemic colitis is diagnosed by a classic appearance of segmental inflamed mucosa on colonoscopy and is generally treated with supportive measures and reversal of the underlying etiology.

Other lesions that can less commonly lead to LGIB include AVMs or Dieulafoy lesions. AVMs are ectatic blood vessels that can be located anywhere in the GI tract but are predominantly found in the cecum and ascending colon. They account for approximately 11% of LGIBs. They may appear as isolated lesions or in clusters of multiple small, flat, red telangiectasias. Dieulafoy lesions are arterial

blood vessels that appear close to the mucosal surface that intermittently bleed. Identifying these vascular lesions can be challenging.

Finally, hemorrhoidal bleeding represents 5% to 10% of acute LGIB. Hematochezia tends to be low volume with little to no clinical significance. Episodes can be isolated or sporadic and often is described by the appearance of blood on the toilet paper or on the outside of stool.

Other causes of LGIB represent a wide variety of possible diagnoses including hemorrhagic infectious diarrhea, colitis from infection, inflammatory bowel disease or radiation change, and malignancy, among others.

DIAGNOSTIC STUDIES AND MANAGEMENT

Similar to UGIB, the gold standard for evaluation of LGIB is endoscopic assessment via colonoscopy, though several other diagnostic tools are available. Patients who present with hematochezia hemodynamic compromise should be evaluated for the possibility of UGIB source. These patients should have NG tube placement with NG lavage to assist in localizing the source of bleeding. Patients with clinical evidence of rapid/ongoing GI blood loss should undergo emergent EGD to rule out UGI etiologies ([Figure 36–2](#)).

Patients with hemodynamic stability and hematochezia should be evaluated first by colonoscopy. The patient should be prepared by using a polyethylene glycol-based solution to cleanse the colon prior to procedure. This can be consumed by having the patient drink the preparation or by administering it through the NG tube. Preparation prior to colonoscopy is essential to facilitate visualization, increase the diagnostic yield of the procedure, and minimize the risk of complication such as perforation. The diagnostic yield of colonoscopy varies widely; patients with diverticular bleeding often have low yield at localization of the bleeding site. Alternate etiologies such as ischemic colitis, vascular lesions, infectious/inflammatory colitis, or malignancy can be diagnosed by colonoscopy. Identification of bleeding diverticula or vascular lesions can be treated endoscopically using the same modalities as

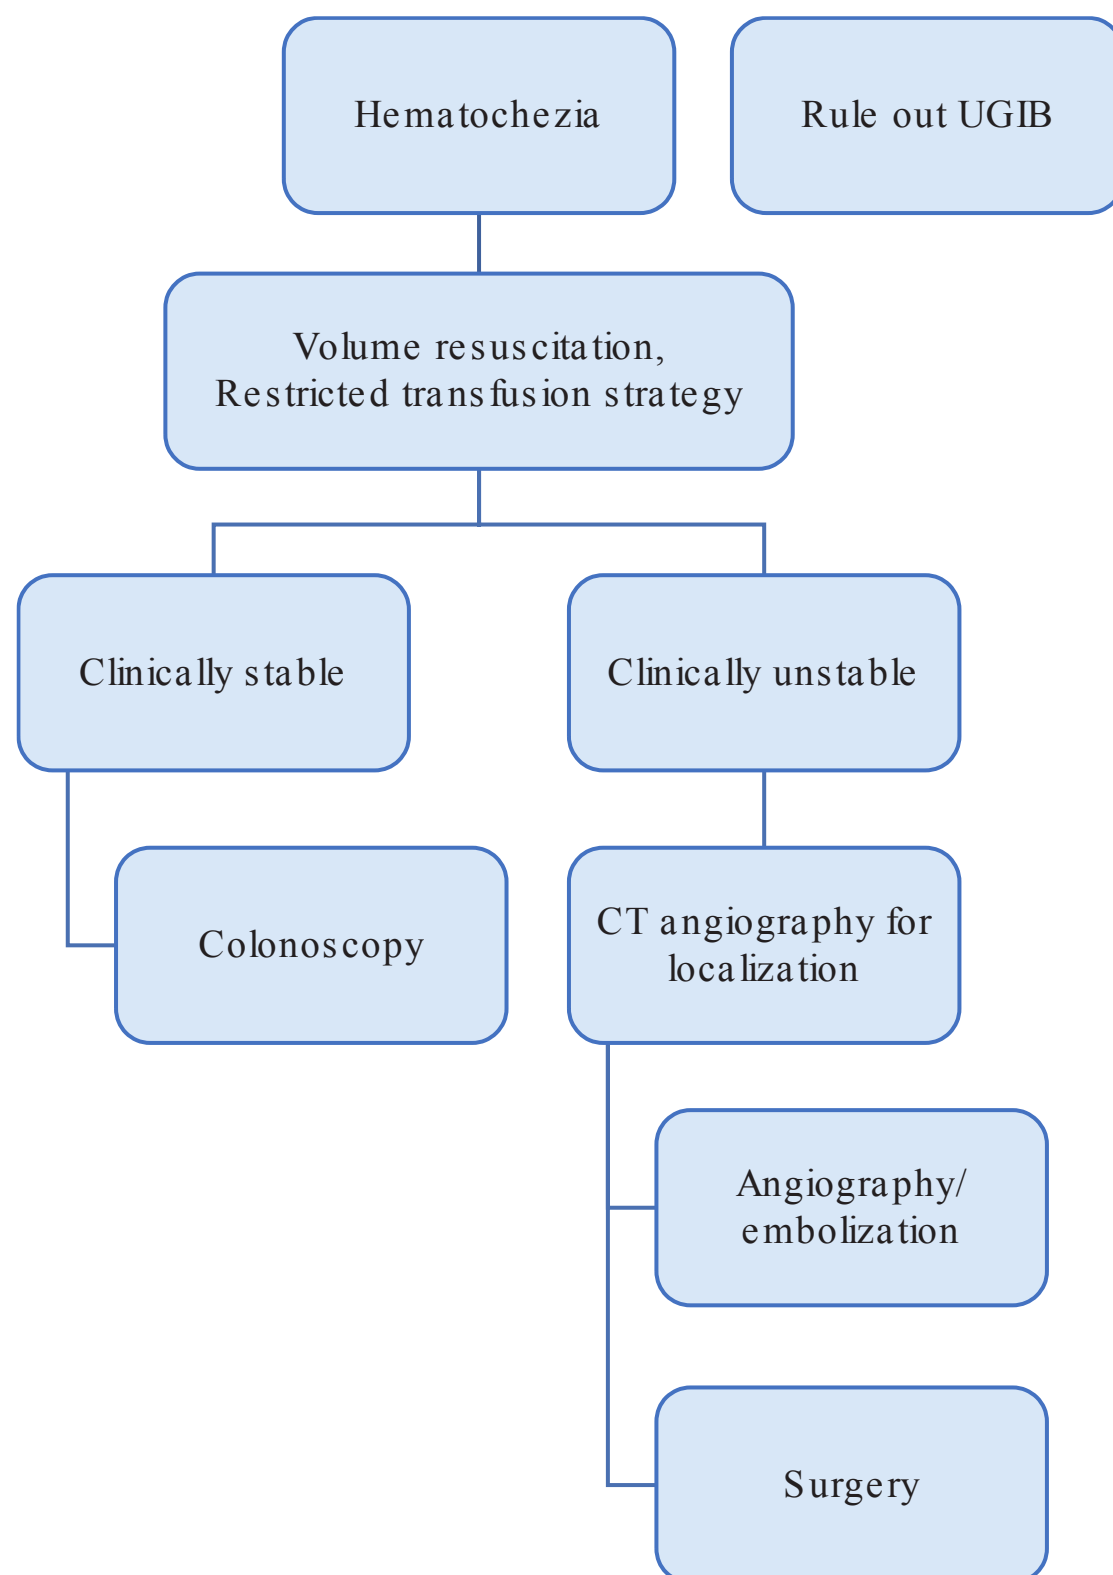

FIGURE 36–2 Management of LGIB.

previously described such as a combination of injection therapy, thermocoagulation, or clip placement.

Patients with nonlocalization of bleeding site and high clinical suspicion for diverticular bleeding can be managed conservatively with close follow-up to assess for ongoing bleeding. If massive bleeding is present, clinical compromise is noted, or ongoing bleeding is suspected, patients may benefit from evaluation by one of several radiologic tests such as CT angiogram, standard angiography, or tagged red blood cell scanning.

The widespread availability of CT angiography has made this a common first test to localize bleeding site. Several studies have demonstrated the high accuracy of CT angiography in identifying and localizing active bleeding either through identification of active extravasation of blood or to localization of intraluminal contents consistent with recent bleeding. The advantage of CT angiography is largely in the ability to perform this evaluation

quickly. If localization is successful, patients are able to undergo subsequent management either through IR-directed percutaneous embolization or through surgical resection. IR-directed embolization is highly effective at treating LGIB and often is used with priority over colonoscopy or surgery in patients who have clinically significant GI bleeding. Tagged red blood cell scans are also able to aid in localization of LGIB but are less in favor than CT angiogram because of the time required to perform the evaluation and its inability to localize the precise source of bleeding/lack of structural imaging.

The determination of which localization modality is optimal in LGIB remains an ongoing discussion and should be handled with a multidisciplinary approach between gastroenterologists, radiologists, and surgeons taking into account the clinical stability of the patient and the time required to prepare for colonoscopy.

CONCLUSIONS

LGIB follows similar principles for management as UGIB; evaluation begins with confirmation of hematochezia and evaluation for a possible UGIB. Evaluating blood loss and resuscitation is the first step in management. Patients who are clinically stable are recommended to undergo preparation followed by colonoscopy for localization and possible treatment of bleeding lesions; patients with hemodynamic instability or ongoing GI blood loss are recommended to undergo CT angiogram for localization of bleeding site followed by conventional angiography and embolization of bleeding vessel or surgery for definitive treatment.

Liver Failure: Acute and Chronic

Brian Kim, MD and Leona Kim-Schluger, MD

KEY POINTS

- 1 Acute liver failure (ALF) is defined as the rapid and severe development of liver dysfunction, marked by encephalopathy and coagulopathy in an individual without a prior history of cirrhosis or liver disease.
- 2 Acetaminophen is the most common cause of ALF in the United States, and prompt administration of N-acetylcysteine helps to decrease mortality in acetaminophen hepatotoxicity. N-acetylcysteine may also have some benefit in nonacetaminophen hepatotoxicity.
- 3 Supportive care remains the mainstay of ALF management. Spontaneous survival rate from ALF is 40% and liver transplantation (LT) remains the only definitive therapy for patients who are unable to achieve timely regeneration of liver mass to maintain life despite adequate supportive care.
- 4 Cirrhosis is characterized by progressive hepatic fibrosis that can lead to consequences of portal hypertension including variceal hemorrhage, ascites, renal failure, and encephalopathy.
- 5 The combination of pharmacologic therapy and endoscopic variceal ligation is effective in controlling bleeding in up to 90% of patients presenting with acute variceal hemorrhage.
- 6 Hepatic encephalopathy is a frequent reason for hospital admissions. Common precipitants, such as infection, dehydration, and bleeding, should be ruled out in any patient presenting with hepatic encephalopathy.

INTRODUCTION

Liver disease results in approximately 35,000 deaths each year, making it the 12th leading cause of death in the United States.¹ Patients suffering from ALF or consequences of chronic liver disease are among the sickest in the hospital. These patients often develop problems that require critical care, and physicians should be knowledgeable about the various complications of liver disease that can be encountered in the intensive care unit (ICU).

Acute Liver Failure

General Considerations

There are an estimated 2000 cases of acute liver failure (ALF) annually, which accounts for 0.1% of all deaths in the United States. Approximately 6% to 7% of all LTs performed in the United States are secondary to ALF.^{2,3}

ALF is defined as the rapid and severe development of liver dysfunction, marked by encephalopathy and coagulopathy with an elevated prothrombin

time (PT) or international normalized ratio (INR), in an individual without a prior history of cirrhosis or liver disease. The exceptions to this definition are in patients who have had previously undiagnosed hepatitis B virus (HBV) infection, hepatitis D virus (HDV) infection with underlying chronic HBV infection, autoimmune hepatitis, or Wilson disease. In these patients, underlying cirrhosis may be present, provided the disease has been recognized for less than 26 weeks.

ALF can be subcategorized by the interval between the development of jaundice and onset of encephalopathy. Common classification cutoffs are: hyperacute (< 7 days), acute (8-28 days), and subacute (28 days-26 weeks). This classification can be clinically useful as cerebral edema is common in hyperacute and acute liver failure whereas complications of portal hypertension are more commonly seen in subacute liver failure.

In the United States, drug-induced hepatitis, especially acetaminophen overdose is the most common cause of ALF in adults. Other causes of ALF are listed in [Table 37–1](#).

Clinical Features

Signs and Symptoms—The symptoms of ALF may vary depending on the severity and etiology. In the case of acetaminophen toxicity, patients may present with rapid onset of abdominal pain, nausea, vomiting, and confusion, several hours after ingestion of acetaminophen. The presentation of ALF due to other etiologies can be more insidious. Patients may present with nonspecific symptoms such as malaise, fatigue, or subtle changes in personality and behavior. New-onset ascites, pruritus, or asymptomatic jaundice can also be seen.

Encephalopathy is a prerequisite to the diagnosis of ALF, and the degree of encephalopathy may be variable from mild to severe ([Table 37–2](#)).

Patients with encephalopathy grade I may have mild asterixis whereas patients with grades II, III, or IV may have overt asterixis or clonus on physical examination. The development of encephalopathy grade III and IV usually heralds the development of cerebral edema and increased intracranial pressure (ICP).

Laboratory Findings—Laboratory testing will reveal a prolonged PT and increased INR greater than 1.5, not correctable by the administration of intravenous (IV) or subcutaneous (SC) vitamin

concurrent acute kidney injury (AKI). AKI occurs in up to 80% of patients with ALF and can occur secondary to hypovolemia, sepsis, or acute tubular necrosis (ATN).⁵ ATN can occur as a result of severe hypotension or, in the case of acetaminophen ingestion, as a result of direct tubular toxicity.⁶ Acidosis is common in ALF as a result of the body’s inability to clear lactic acid in the setting of severe hepatic necrosis and concurrent AKI. The severity of laboratory abnormalities and encephalopathy can be used to help predict patient outcomes (Table 37–3).

Treatment

ALF is a medical emergency with high rates of multisystem organ failure and high mortality without appropriate management. Only 40% of patients diagnosed with ALF have spontaneous recovery.⁸ Thus, all patients presenting with ALF should be managed in a center with an active liver transplant program.

Patients with grade I encephalopathy can be managed with care in a general medical ward, provided that they undergo frequent neurologic checks (every 2 hours) to identify signs of progression to higher grades of encephalopathy. Grade II encephalopathy and higher should be managed in the ICU.

Specific etiologies of ALF may have specific management options that can help avoid LT and decrease mortality (Table 37–4). Of special note, N-acetylcysteine, which is the antidote of choice for acetaminophen toxicity, may also be of benefit in other forms of ALF. The administration of NAC has been shown to increase transplant-free survival in patients with grade I and II encephalopathy, presenting with nonacetaminophen ALF.⁹

Regardless of the etiology, supportive measures remain essential in the management of ALF patients.

Supportive Measures

Cerebral Edema and Intracranial Hypertension—Cerebral edema leading to intracranial hypertension remains the major cause of mortality in patients presenting with ALF. The pathogenesis of cerebral edema is not clearly understood in ALF and likely is secondary to multiple factors including the breakdown of the blood-brain barrier, neurotoxin release, and resultant osmotic disturbances. The predictors

TABLE 37–4 Specific etiologies of acute liver failure and potential treatments.

Acetaminophen toxicity	N-acetylcysteine
Mushroom toxicity (<i>Amanita phalloides</i>)	Penicillin G or silymarin
Valproate	Carnitine
Hepatitis B virus +/- hepatitis D virus	Antiviral nucleo(s)tide (eg, entecavir, tenofovir, lamivudine, adefovir, telbivudine)
Herpes simplex virus	Acyclovir
Budd-Chiari syndrome	Transjugular intrahepatic portosystemic shunt placement, surgical shunt placement, or thrombolysis
Autoimmune hepatitis	Prednisone
Wilson disease	Usually will require liver transplantation but plasma exchange can be a temporizing measure
Acute fatty liver of pregnancy	Expedited delivery of the fetus

of cerebral edema include high-grade encephalopathy (grade III/IV) and increased arterial ammonia concentration ($> 200 \mu\text{mol/L}$).^{10,11}

Simple interventions may be beneficial to reduce intracranial hypertension in patients with grade III/IV encephalopathy. Tracheal intubation with sedation, elevation of the head to 30° , minimization of painful stimuli, and control of arterial hypertension should be initiated universally. A quiet environment should be maintained to reduce external stimuli, and premedication should be given prior to tracheal suctioning or patient positioning to minimize changes in ICP.

The use of ICP monitoring devices in ALF is controversial, and its use is largely dependent on local practices. The decision to place an ICP monitoring device should be made after discussion with the ICU, transplant hepatology, and neurosurgery teams.

If the patient does develop increased ICP as evident by direct ICP monitoring or neurologic examination (pupillary abnormality or decerebrate posturing), further measures to reduce ICP should be initiated. The goal of therapy is to reduce the ICP to below 20 to 25 mm Hg while maintaining cerebral perfusion pressure (CPP) above 50 to 60 mm Hg.

Mannitol causes osmotic diuresis and has been shown to decrease ICP. Its use has been associated with improved survival in ALF.^{12,13} Patients can be given bolus doses of mannitol to decrease ICP, provided that serum osmolality does not exceed 320 mOsm/L. The use of mannitol is limited in the setting of volume overload and renal failure. Hypertonic sodium chloride (30% normal saline [NS]) can also be considered to maintain serum (Na) levels of 145 to 155, to prevent a rise in ICP.¹⁴

Hyperventilation to reduce Paco_2 quickly lowers ICP via vasoconstriction and decrease in cerebral blood flow. However, this effect is short lived and does not adequately lower ICP long term.¹⁵

Seizure—Seizure activity in patients with ALF is common but difficult to detect in intubated and sedated patients. Seizures should be treated promptly as seizure activity can acutely increase ICP and cause cerebral edema.¹⁶

Infection—Infection is a major contributor to mortality in patients presenting with ALF. All patients with ALF are at increased risk for bacterial and

fungal infections. Common sites of infection include the respiratory tract, urinary tract, and blood. Routine surveillance cultures should be obtained from the sputum, urine, and blood along with chest radiograph to detect infections early, as severe sepsis increases mortality as well as precludes potential LT. Prophylactic antibiotic use is controversial but can be considered in patients with severe encephalopathy. Empiric antibacterial and antifungal antibiotics should be started if patients present with worsening hypotension or renal failure, as early signs of infection.

Coagulopathy—Coagulopathy, marked by prolonged PT and INR, is universal in patients presenting with ALF. PT/INR is one of the predictors of outcomes in ALF (see Table 37–3), and thus, empiric correction of PT/INR with fresh frozen plasma (FFP) should be held unless patients have signs of overt bleeding or are in need of an invasive procedure. If a patient has signs of overt bleeding or is in need of an invasive procedure, such as ICP monitoring device placement, FFP and/or recombinant human factor VIIa can be used to help reverse the coagulopathy. However an increasing body of data suggests that routine correction of PT/INR is not necessary prior to percutaneous vascular access procedures, paracentesis, and other nonneurosurgical procedures in patients with liver disease.

Renal Failure—AKI can be seen in 55% to 80% of patients presenting with ALF.^{5,17} Maintenance of euvolemia is critical and determination of preload responsiveness via echocardiography should be considered to manage volume status. Nephrotoxic drugs such as aminoglycosides should be avoided and renal replacement therapy (RRT) may need to be initiated in setting of worsening renal function. If patient requires RRT, continuous rather than intermittent RRT is recommended to avoid large fluid shifts that may impact ICP.

Cardiovascular Support—ALF is characterized by high cardiac output with low systemic vascular resistance secondary to decreased clearance of vasoactive metabolites. Vasopressor drugs may be required to maintain adequate systemic mean arterial pressure (MAP) and CPP.

Respiratory Failure—Acute respiratory distress syndrome (ARDS) occurs in one-third of patients presenting with ALF and can cause significant

hypoxemia that requires low tidal volume and high positive end-expiratory pressure (PEEP) to achieve adequate tissue oxygenation.¹⁰ The lowest possible PEEP should be used as high PEEP ventilation can exacerbate cerebral edema and hepatic congestion. Nutrition—Hypoglycemia is common in ALF due to severe hepatic necrosis that impairs glycogenolysis and gluconeogenesis. Frequent serum glucose monitoring should be instituted, and profound hypoglycemia should be managed with continuous glucose infusion. Hyperglycemia should be avoided as it may contribute to poor ICP control.

Owing to the catabolic state of ALF, enteral nutrition should be initiated as early as possible. **Liver Transplantation**—Liver transplantation remains the only definitive therapy for patients who are unable to achieve timely regeneration of liver mass to maintain life. Spontaneous survival rate from ALF is 40%, as compared to posttransplantation survival rate of greater than 80%.⁸ Although imperfect, the King’s College Criteria is most often used to help triage those that may benefit from LT (see Table 37–3).

Early involvement of a multidisciplinary LT team is essential to determine if a patient is a suitable organ recipient, medically, psychologically, and socially. Timely evaluation for LT is essential; as high as 37% of patients die despite being listed for LT due to the shortage of available organs.¹⁸

Chronic Liver Failure

General Considerations

Cirrhosis is characterized by progressive hepatic fibrosis and represents the final, common pathway of a variety of chronic liver diseases (Table 37–5). With progressive injury to the liver, patients with cirrhosis can have consequences of liver dysfunction, such as jaundice, coagulopathy, and hypoalbuminemia. Scarring and architectural distortion of the liver lead to portal hypertension with resultant ascites, variceal formation, hepatic encephalopathy (HE), thrombocytopenia, and renal failure. These consequences of cirrhosis lead to increased morbidity and mortality, especially in patients with high Model for End-Stage Liver Disease (MELD) scores. Liver transplantation remains the only definitive treatment for complications from cirrhosis.

Acute Gastrointestinal Bleeding From Esophageal Varices

General Considerations

Gastroesophageal varices form as a result of increased portal pressures and occur in about 50% of patients with cirrhosis. Usually, the hepatic venous pressure gradient (HVPG) must be at least 12 mm Hg for varices to form.¹⁹ Hemorrhage from varices occurs at a yearly rate of 6% to 76%, depending on the size of the varices and the severity of the underlying liver disease.²⁰ The mortality of patients presenting with variceal hemorrhage approaches 20%.²¹ Early identification of gastroesophageal varices is important as prophylaxis with beta-blockade or endoscopic variceal ligation (EVL) decreases the risk of variceal hemorrhage.

Clinical Features

Signs and Symptoms—Patients with hemorrhage from gastroesophageal varices present with hematemesis or melena. Patients often present with hemodynamic instability marked by tachycardia and hypotension.

Laboratory Findings—Anemia occurs frequently, but a decrease in hemoglobin level may not be detected early in the course of hemorrhage.

Differential Diagnosis

Similar clinical presentation can be seen in other etiologies of upper gastrointestinal hemorrhage such as from peptic ulcer diseases, Mallory-Weiss tears, and Dieulafoy lesions.

Treatment

Patients with suspected acute variceal hemorrhage should be managed in an ICU. The need for airway protection with tracheal intubation should be assessed early. Adequate peripheral venous access should be obtained and volume resuscitation started to maintain hemodynamic stability. Transfusions with FFP and platelets should be considered in patients with severe coagulopathy and thrombocytopenia.

However, red blood cell transfusion should be used cautiously in patients with suspected variceal hemorrhage. Overtransfusion may propagate bleeding due to increased portal pressures. Prospective, randomized data suggest that restricting red blood cell transfusions improves outcomes in acute variceal hemorrhage. A restrictive transfusion strategy (transfusion when hemoglobin falls below 7 g/dL) compared to a liberal transfusion strategy (transfusion when hemoglobin falls below 9 g/dL) resulted in lower rates of death, rebleeding, and adverse events.²² Of note, the study excluded patients presenting with massive exsanguination. In these patients, it may be prudent to initiate volume resuscitation and transfuse blood products to help maintain hemodynamic stability prior to obtaining hemoglobin levels.

Pharmacologic Therapy

Vasoactive Drugs—Vasoactive drugs should be started as soon as a variceal hemorrhage is suspected. These drugs can temporize bleeding prior to more definitive treatment modalities.

The somatostatin analog, octreotide, causes splanchnic vasoconstriction and is a safe pharmacologic therapy to decrease portal pressures. It is given as a bolus infusion of 50 µg IV followed by a continuous infusion at 25 to 50 µg/h. Meta-analysis suggests improved outcomes with the use of octreotide as compared to placebo when paired with EVL.²³

Despite routine outpatient use to reduce portal pressures, beta-blockers should not be used during acute hemorrhage as it decreases systemic blood pressure and blunts physiologic increase in heart rate associated with acute hemorrhage.

Antibiotic Prophylaxis—Cirrhotic patients with upper gastrointestinal bleeding have high rates of developing severe bacterial infections including spontaneous bacterial peritonitis (SBP), urinary tract infection, and bacteremia. Trials have shown that short-term antibiotic prophylaxis given at presentation and continued for 7 days improves infection rates as well as survival after variceal hemorrhage.²⁴ Oral norfloxacin 400 mg twice daily or IV ceftriaxone 1 g once daily can be used.

Endoscopic Treatment—For suspected variceal hemorrhage, early endoscopy (< 12 hours after presentation) is recommended. For esophageal variceal hemorrhage, EVL should be used to control bleeding. When combined with pharmacologic therapy, EVL is effective in controlling bleeding in up to 90% of patients.²⁵

Gastric type varices are seen in about 20% of patients with portal hypertension.²⁶ Active gastric variceal hemorrhage has a poor response to EVL and sclerotherapy. Endoscopic variceal obturation with tissue adhesive such as N-butyl-cyanoacrylate, isobutyl-2-cyanoacrylate, or thrombin is more effective, controlling bleeding in 90% of patients.²⁷ However, variceal obturation is not routinely practiced, and its use may be limited by local expertise.

In those with early rebleeding, repeat attempt at endoscopic intervention can be considered. If hemorrhage cannot be controlled, balloon tamponade can be used as a temporizing measure to control bleeding in 80% of patients.²⁸

Shunt Procedures—The placement of a transjugular intrahepatic portosystemic shunt (TIPS) is an effective way to decrease portal pressures and is

now widely used as an option to control refractory bleeding from esophageal and gastric type varices. A reduction in HVPG to below 12 mm Hg or a reduction in HVPG greater than 20% from baseline appears to effectively eliminate the risk of rebleeding.^{29,30} Caution should be taken in patients with heart failure, pulmonary hypertension, and intrinsic renal failure as the extra shunting of blood volume into the systemic circulation may not be handled appropriately in these patients. By increasing shunting from the portal vasculature to the systemic vasculature, TIPS placement may also worsen symptoms of HE. Elective TIPS procedure in a patient with a high MELD score (> 18) is relatively contraindicated as it may precipitate worsening liver dysfunction.³¹ The presence of hepatocellular carcinoma (HCC) is also a relative contraindication to TIPS placement as it may promote vascular seeding.

Surgical shunt procedures such as portacaval, mesocaval, and splenorenal shunt procedures have been used successfully to control refractory bleeding but have now fallen out of favor given the effectiveness of the TIPS procedure.

Balloon-Occluded Retrograde Transvenous Obliteration—Balloon-occluded retrograde transvenous obliteration (BRTO) is a technique that is widely used in Asia to treat gastric varices. BRTO is a fluoroscopically guided transcatheter procedure used to introduce sclerosants into gastric varices. It relies on the presence of a gastorenal or gastrocaval shunt to access the varices. If the appropriate shunt is identified on cross-sectional imaging, BRTO can be considered to treat gastric varices in select centers with local expertise.³² BRTO has been shown to control bleeding in up to 88% of patients with active gastric variceal bleeding.³³

Ascites

General Considerations

Ascites is the pathologic accumulation of fluid in the peritoneal space, and cirrhosis accounts for 85% of cases.³⁴ Ascites is one of the most common complications of cirrhosis, developing in 58% of patients within 10 years of the diagnosis of cirrhosis.³⁵ Patients who develop ascites have a 1-year mortality of 15% and 5-year mortality of 44%.³⁶

Clinical Features

Symptoms and Signs—Patients presenting with large-volume ascites complain of increased abdominal girth and discomfort. Nausea, early satiety, and anorexia are common symptoms. Clinical examination can reveal a distended abdomen with shifting dullness and the presence of fluid waves.

Laboratory Findings—A diagnostic paracentesis should be performed in all patients presenting with new-onset ascites. Inspection of the ascitic fluid can help determine the etiology of ascites. A serum albumin-ascites gradient (SAAG) should be calculated in all new-onset ascites. A SAAG greater than or equal to 1.1 g/dL has a 97% sensitivity for the detection of portal-hypertensive ascites.³⁴ A protein level greater than 2.5 g/dL in the ascitic fluid can further help classify portal-hypertensive ascites into the category of cardiac ascites.³⁷

Treatment

Medical Treatment

Diuretics—Minimal ascites can be managed effectively with a Na-restricted diet (2 g/d). In patients with moderate ascites, the addition of diuretic regimen consisting of a loop diuretic (eg, furosemide) and aldosterone inhibitor (eg, spironolactone) is effective in controlling ascites in 90% of patients.³⁸ The combination works better than either diuretic alone and helps to maintain normokalemia. Initial dose of 40 mg daily of furosemide and 100 mg daily of spironolactone is usually well tolerated by patients. If serum Cr and electrolytes remain stable, the diuretic dose can be increased in a step-wise fashion up to 160 mg daily for furosemide and 400 mg daily for spironolactone. Daily weight loss of 1 kg until euvolemia is appropriate.

Paracentesis—In less than 10% of patients, ascites can be refractory to Na-restricted diet and diuretics. These patients may benefit from serial large-volume paracentesis (LVP). LVP is safe and effective in removing large amounts of ascites at one time. Even in the absence of urine output, ascites can be well controlled when performed every other week.³⁹ LVP can significantly increase plasma renin and serum Cr; however, this effect can be tempered by the use of albumin replacement.⁴⁰ Typically 25% IV albumin at a dose of 8 g per 1 L of ascites removed is given to

attenuate the electrolyte and fluid shift changes seen after LVP.

Shunt Procedures—An alternative to serial LVP is the TIPS procedure. Several trials have shown improved control of ascites in the TIPS group as compared to serial LVP.^{41,42} However, TIPS should be placed with extreme caution in patients with severe HE, heart failure, pulmonary hypertension, intrinsic renal disease, HCC, and high MELD scores (> 18).

Spontaneous Bacterial Peritonitis

General Considerations

SBP is an infection of the ascitic fluid without a surgically treatable intra-abdominal source and most commonly occurs as a complication of ascites from advanced cirrhosis.⁴³ SBP is diagnosed in 12% of hospitalized patients with cirrhosis and ascites.⁴⁴ In-hospital mortality of SBP can be up to 33%.⁴⁵

Clinical Features

Symptoms and Signs—Patients may present with fever and abdominal tenderness, but often the presenting symptoms may be subtle, such as confusion and fatigue. Approximately 13% of patients with the diagnosis of SBP have no signs or symptoms of infection.⁴⁶ SBP should be suspected in any patients presenting with signs of hepatic decompensation in the setting of cirrhosis and ascites.

Laboratory Findings—Diagnosis of SBP is by the presence of an ascitic fluid absolute polymorphonuclear leukocyte (PMN) count greater than 250 cells/mm³.⁴⁷ Gram stain and cultures should be sent from the ascitic fluid, but the yield can be low in identifying the offending organism. Concurrent blood culture can increase the diagnostic yield of identifying an organism.

Treatment

As PMN count results are available more quickly than culture results, patients with ascitic PMN counts greater than 250 cells/mm³ should be treated with broad-spectrum antibiotics. The 3 most common organism isolates are *Escherichia coli*, *Klebsiella pneumoniae*, and *Streptococcal pneumoniae*. Empiric treatment with third-generation cephalosporin such as ceftriaxone or cefotaxime appears to be effective in covering 95% of cases.⁴⁸ After antibiotic sensitivities of the organism are obtained, the antibiotic

coverage can be adjusted accordingly. If no clinical improvement is seen in 48 hours, a repeat diagnostic paracentesis should be considered to assess the PMN response and to document sterility of the ascites.

Hepatorenal Syndrome

General Considerations

Hepatorenal syndrome (HRS) is the development of renal dysfunction in the setting of cirrhosis and ascites. Progressive portal hypertension and splanchnic vasodilatation are followed by fall in systemic vascular resistance. Relative renal hypoperfusion occurs with resultant vasoconstriction of the renal circulation and drop in glomerular filtration rate (GFR).

HRS is divided into 2 types. Type I is characterized by the rapid and progressive impairment in renal function with associated oliguria. Without treatment, type I HRS is uniformly fatal. Type II HRS develops more slowly and is marked by relatively mild reduction in renal function. Typically, patients with type II HRS present with diuretic-resistant ascites. The diagnostic criteria for HRS are listed in Table 37–6.

Clinical Features

Signs and Symptoms—Patients present with signs of progressive renal failure. Volume overload can be seen with oliguria. Signs of uremia may be present, including progressive confusion.

Laboratory Findings—Serum Cr is greater than 1.5 mg/dL with concurrent BUN elevation. Urinary Na concentration less than 10 mEq/L and serum Na

TABLE 37–6 Diagnostic criteria for the hepatorenal syndrome.⁴⁹

1. Presence of cirrhosis with ascites
2. Serum creatinine greater than 1.5 mg/dL
3. No improvement of serum creatinine (decrease to level < 1.5 mg/dL) after at least 2 ds with diuretic withdrawal and volume expansion with albumin (1 g/kg of body weight per day up to a maximum of 100 g/d).
4. Absence of shock
5. No current or recent treatment with nephrotoxic drugs
6. Absence of parenchymal kidney disease as indicated by proteinuria greater than 500 g/d, microhematuria (> 50 red blood cells per high-power field), and/or abnormal renal ultrasonography

Reproduced with permission from Salerno F, Gerbes A, Ginès P, et al: Diagnosis, prevention and treatment of hepatorenal syndrome in cirrhosis, *Postgrad Med J*. 2008 Dec;84(998):662-670.

concentration less than 130 mEq/L are often seen in patients with HRS.

Differential Diagnosis

Other causes of AKI should be excluded, as patients with cirrhosis may be especially susceptible to prerenal azotemia and ATN. Patients should be questioned about recent use of nephrotoxic drugs such as nonsteroidal anti-inflammatory drugs or aminoglycosides.

Treatment

Pharmacologic Therapy—Initial management of patients presenting with renal failure should be volume resuscitation to exclude prerenal azotemia. Albumin (1 g/kg of body weight per day, up to a maximum of 100 g/d) should be given. If no improvement in renal function is seen and HRS is suspected, an attempt at pharmacologic therapy should be attempted.

Terlipressin is the drug studied most extensively to treat HRS. In combination with albumin, it has been shown to have 50% efficacy in reversing HRS.⁵⁰ Terlipressin is currently not available in the United States.

The combination of oral midodrine (7.5–12.5 mg 3 times daily), SC octreotide (100–200 µg 3 times daily), and IV albumin may be utilized as an alternative to terlipressin. The combination appears to be effective in lowering serum creatinine and 30-day mortality.⁵¹

For patients in the ICU, albumin and continuous IV norepinephrine can be attempted to reverse type I HRS.⁵²

Renal Replacement Therapy—More often, patients with type I HRS are unresponsive to pharmacologic therapy, and RRT is required to manage electrolyte imbalance and volume overload. Expedited LT evaluation should be performed in these patients, as the development of type I HRS is a predictor of poor outcome.

Hepatic Encephalopathy

General Considerations

Hepatic encephalopathy is a reversible impairment in neuropsychiatric function associated with hepatic dysfunction. The exact pathophysiology of HE in chronic liver disease remains unclear, but a

Malignancy
Medication noncompliance

combination of elevated ammonia level along with alteration in blood-brain barrier leads to changes that activate inhibitory neurotransmitters (gamma-aminobutyric acid, [GABA], serotonin) and impair excitatory neurotransmitters (glutamate, catecholamine). Overt HE is present in 30% of patients with cirrhosis and is a frequent reason for hospital admissions.⁵³ Common precipitants of HE are listed in [Table 37–7](#).

Clinical Features

Symptoms and Signs—Patients can present with varying degrees of neuropsychiatric dysfunction, ranging from subtle cognitive deficits to overt coma (see [Table 37–2](#)).

Laboratory Findings—Patients will have abnormal liver function tests, reflective of their underlying liver disease. Electrolyte disturbances may be seen that can precipitate HE. Patients may have elevated arterial and venous ammonia levels. However, an elevated ammonia level is not required to make the diagnosis of HE, and the level often does not correlate with the degree of encephalopathy.

Treatment

General supportive care should be provided to patients presenting with HE. Appropriate triage of patients should be made depending on the severity of encephalopathy. Patients with agitation or confusion may need close supervision to avoid injury. In patients presenting with grade IV encephalopathy, observation in an ICU may be appropriate with consideration for tracheal intubation for airway protection.

The treatment of HE begins with the correction of any underlying, precipitating factors, including infection, bleeding, dehydration, electrolyte abnormality, and renal dysfunction.

Treatment with lactulose, a synthetic disaccharide, is the mainstay of therapy for overt HE despite limited evidence from randomized trials.⁵⁴ Lactulose is metabolized by the colonic flora and lowers colonic pH. The resultant pH favors the formation of nonabsorbable NH_4^+ from NH_3 , thus reducing plasma ammonia concentration. Lactulose also works to clear ammonia via its osmotic laxative effect. Oral or rectal lactulose can be given for acute overt HE until mental status improves. Once HE resolves, the drug dose can be titrated to achieve 2 to 3 soft bowel movements per day.

In combination with lactulose, rifaximin, a nonabsorbable antibiotic, has been shown to maintain remission of HE.⁵⁵ Rifaximin 550 mg twice daily or 400 mg 3 times daily is effective in controlling HE with minimal reported adverse effects. Other antibiotics such as metronidazole and neomycin have been used for HE. However, concern for long-term side effects including neuropathy for metronidazole and ototoxicity for neomycin has limited their chronic use in HE.

l-Ornithine l-aspartate, zinc, branched-chain amino acids, flumazenil, and sodium benzoate have all been used with variable success in HE and may be options in the setting of brittle encephalopathy.

Fever in the ICU

Anuja Pradhan, MD and Daniel Caplivski, MD

KEY POINTS

- 1 Fever should prompt investigation into potential infectious as well as noninfectious etiologies.
- 2 Treatment with empiric antibiotics may be indicated in particular in patients with other signs of sepsis such as tachycardia and hypotension.
- 3 Fever may also be caused by potentially life-threatening noninfectious syndromes such as thromboembolic disease and it is important to investigate these possibilities as well.

INTRODUCTION

Fever is a state of elevated core temperature that is often a sign of infection in patients admitted to the intensive care unit (ICU). It should prompt investigation into potential infectious as well as noninfectious etiologies. Treatment with empiric antibiotics may be indicated in particular in patients with other signs of sepsis such as tachycardia and hypotension. Fever may also be caused by potentially life-threatening noninfectious syndromes such as thromboembolic disease and it is important to investigate these possibilities as well.

PATHOPHYSIOLOGY

The febrile response, of which temperature rise is a component, is a complex physiologic reaction to disease, involving cytokine-mediated rise in core temperature, generation of acute phase reactants, and activation of numerous physiologic, endocrinologic, and immunologic systems. In contrast, simple heat illness or malignant hyperthermia is

an unregulated rise in body temperature caused by inability to eliminate heat adequately. Fever begins with the production of one or more proinflammatory cytokines in response to exogenous pyrogens (microorganisms, toxic agents) or immunologic mediators. Interleukin 1 (IL-1), tumor necrosis factor (TNF), lymphotoxin, interferons (IFNs), and interleukin 6 (IL-6) are known and documented to induce fever independently. Cytokines interact with receptors located at the organum vasculosum of the lamina terminalis causing synthesis and release of prostaglandins, chiefly prostaglandin E₂, which raises body temperature by initiating local cAMP production, which resets the thermoregulatory set point of the hypothalamus and by coordinating other adaptive responses such as shivering and peripheral vasoconstriction. Fever induces the production of heat shock proteins (HSPs), a class of proteins critical for cellular survival during stress. HSPs may have an anti-inflammatory role and indirectly decrease the level of proinflammatory cytokines. Core body temperature may be influenced by numerous external factors including cooling

blankets or continuous venovenous hemofiltration. Patients who have suffered neurologic injury or central nervous system (CNS) hemorrhage may also have hypothalamic dysfunction that could lead to elevated body temperature.

EPIDEMIOLOGY

The incidence of fever in the ICU ranges from 28% to 70%. Infectious as well as noninfectious etiologies contribute almost equally to the causation of febrile episodes. The finding of a new fever in an ICU patient has a significant impact on health care costs due to the blood cultures, radiologic imaging, and antibiotics that are often empirically initiated. It is therefore important to have a good understanding of the mechanisms and etiology of fever in ICU patients, how and when to initiate a diagnostic workup, and when initiation of antibiotics is indicated.

DIAGNOSTIC APPROACH TO THE FEBRILE PATIENT IN THE ICU

A new fever in a patient in the ICU should trigger a careful clinical assessment rather than automatic orders for laboratory and radiologic tests. A cost-conscious approach to obtaining cultures and imaging studies should be undertaken if indicated after a clinical evaluation.

History and Physical Examination

Many patients admitted to the ICU are not able to provide direct information about localizing complaints. In patients who are intubated or obtunded information should be obtained from medical records regarding relevant antecedent problems (eg, previous infections, cancer, allergic reactions to drugs, immunosuppression etc). Relatives and friends of the patient may also provide pertinent epidemiologic information related to the patient's exposures and risk factors for infections. Physical examination of the febrile ICU patient should include examination of devices including intravenous catheters, endotracheal and nasogastric tubes, and bladder catheters. Skin examination may demonstrate findings suggestive of drug reaction,

vasculitis, infective endocarditis, or soft tissue infection. All intravenous and intra-arterial line sites should be inspected for signs of erythema, warmth, tenderness, and purulence. All surgical wounds should be examined 24 hours postoperatively. Head and neck examination may reveal important signs of localized and systemic infection. Funduscopic examination may provide clues to systemic viral or fungal infection, particularly in immunocompromised patients. Oral lesions of recrudescing herpetic stomatitis are common in the ICU setting and may be obscured by the presence of oral endotracheal tubes or orogastric feeding tubes. These lesions may be extensive, more ulcerated and necrotic, and less vesicular in appearance in a seriously ill patient. Examination of the lungs can be difficult in the intubated ICU patient and often is unrewardingly nonlocalizing and nonspecific. Abdominal findings can be misleadingly unremarkable in the elderly, in the patient with obtunded sensorium, and in the patient receiving sedatives and can be confounding in the patient with recent abdominal or thoracic surgery. Abdominal pain and tenderness may be localized (cholecystitis, intra-abdominal abscess, diverticulitis) or generalized (diffuse peritonitis, ischemic bowel, antibiotic-associated colitis). Examination of the genitalia and rectum may demonstrate unsuspected epididymitis, prostatitis, prostatic abscess, or perirectal abscess.

INFECTIOUS CAUSES OF FEVER IN THE ICU

Catheter-Associated Bloodstream Infections

Catheter-associated bloodstream infections are one of the most common reasons for patients to have fever in the ICU. Central venous and arterial catheters are important tools for monitoring patients and delivering fluids, antibiotics, nutrition, and other therapies. Bacteria and yeast that colonize the skin of the patient or the hands of health care providers can easily gain access to the circulation via these devices. The risk of infection from these catheters is variable and depends on several factors such as length of the catheter, type of catheter such as arterial versus venous, tunneled versus nontunneled, technique

of insertion, site of insertion, duration they have been in place, frequency of manipulation, patient population etc (Table 38–1). The highest risk is with short-term, noncuffed central venous catheters, in the range of 2 to 5 per 1000 catheter-days. There are several mechanisms, which may lead to the infection of an indwelling catheter. Skin pathogens can infect the catheter exit site or contaminate the catheter hub, leading to intraluminal catheter colonization and infection. Parenteral fluid, blood products, or intravenous medications can also be a source of infection. The catheter exit site should be inspected daily for evidence of erythema or pus; however these signs are absent in most cases with catheter-related bloodstream infection. Any expressible purulence or exudate should be sent for Gram stain and culture. Gram-positive organisms such as *Staphylococcus aureus*, coagulase-negative *Staphylococcus*, and *Enterococcus* species are commonly responsible for catheter-associated bloodstream infections. Increasingly these organisms have acquired resistance to beta-lactam antibiotics and even vancomycin. Many gram-positive organisms are also capable of forming biofilms which make them difficult to eradicate and removal of the central venous catheter is

generally necessary for successful treatment of these infections.

Gram-negative organisms are also important cause of catheter-associated bloodstream infections. Enterobacteriaceae such *Escherichia coli*, *Klebsiella pneumoniae*, and *Enterobacter* species are considered normal flora of the gastrointestinal (GI) tract; however they may colonize the hubs and tubing of central catheters and they may eventually be a cause of bacteremia. *Pseudomonas aeruginosa* is another important gram-negative organism that is often associated with nosocomial infection, including catheter-associated bacteremia. Because of the production of endotoxin gram-negative organisms are likely to trigger the release of cytokines that clinically manifest with signs of sepsis. In the hospital environment many gram-negative organisms have acquired multiple antibiotic resistance mechanisms. In addition to production of extended-spectrum beta-lactamase, several gram-negative species have also acquired carbapenemases that have made them resistant to the carbapenem class of antibiotics. The spread of these organisms within ICUs and throughout health care institutions more generally has been a particular challenge for infection control programs.

Candida bloodstream infections are also a common source of fever in the ICU. The use of central venous catheters to deliver total parenteral nutrition and empiric broad-spectrum antibacterial agents are important risk factors for *Candida* bloodstream infections. Catheter removal is of particular importance in the setting of fungemia as these infections are typically very difficult to eradicate when the infected catheter has not been removed. *Candida albicans* is frequently recovered from blood cultures in these patients; however increasingly nonalbicans species are responsible for these types of infection. Empiric therapy for *Candida* bloodstream infections should be guided initially by the severity of the infection as well as the epidemiology of *Candida* species as several nonalbicans species are resistant to fluconazole.

TABLE 38–1 Infectious causes of fever in the ICU.

Most common
Catheter-related bloodstream infection
Ventilator-associated pneumonia
Primary septicemia/bacteremia
Surgical site/wound infection
Other causes
Sinusitis
Intra-abdominal abscess
Empyema
Diverticulitis
Cholangitis
Cellulitis
Soft tissue infections including necrotizing fasciitis and myonecrosis
Infected decubitus ulcer
Endocarditis
Suppurative thrombophlebitis
Septic arthritis
Urinary tract infections
Septic arthritis
<i>Clostridium difficile</i> colitis

Pulmonary Infection Including Ventilator-Associated Pneumonia

Pneumonia is the second most common cause of infection acquired in the ICU and ventilator-associated pneumonia (VAP) is a common source of

fever in the intubated patient. Between 10% and 25% of patients on mechanical ventilation will develop VAP during their ICU stay. Several factors increase the risk of patients in the ICU for developing pneumonia including endotracheal intubation and altered levels of consciousness associated with primary processes or with sedation for mechanical ventilation. Cough responses normally important as a host defense may be impaired by these and other factors, including age over 60, male gender, chronic lung disease, aspiration, acute respiratory distress syndrome (ARDS), sinusitis, nasogastric tube use, delayed extubation, continuous sedation, use of paralytic agents, and endotracheal cuff pressures less than 20 cm of H₂O.

Nosocomial pathogens such as *Pseudomonas* and methicillin-resistant *S aureus* are more commonly associated with patients in the ICU. Precise microbiologic diagnosis is often challenging since obtaining an appropriate sputum sample or endotracheal aspirate is difficult in patients who are intubated. Organisms that colonize the airways may not reflect the true etiology of a lower respiratory tract infection in a patient with nosocomial pneumonia and sputum cultures should be interpreted with caution. High-quality sputum or bronchoalveolar lavage specimens with few squamous epithelial cells and many polymorphonuclear cells may be useful to guide antibiotic therapy. A higher-resolution study such as computerized tomography (CT) may be pursued if clinical suspicion is high enough and it may be helpful for detecting infiltrates in the posterior-inferior lung bases. Fiberoptic bronchoscopy with transbronchial biopsy may be especially useful for the detection of pathogens such as *Pneumocystis jiroveci*, *Aspergillus* species and other filamentous fungi, *Nocardia*, *Legionella*, cytomegalovirus (CMV), and *Mycobacterium* species. Thoracentesis can also be performed on patients with significant pleural effusions. Fluid should be sent for cell count, chemical analysis, and culture, especially if there is adjacent pulmonary infiltrate, suspicion of tuberculosis, or possible contamination of the pleural space due to surgery, trauma, or a fistula.

Urinary Tract Infection

Catheterization of the bladder is a common practice in ICUs for several reasons including close monitoring of fluid balance. Urinary tract infection can be

a cause of fever for patients in the ICU, particularly if there is some obstruction to urinary flow such as nephrolithiasis or ureteral blockage by tumor. Colonization of urinary catheters by resistant organisms such as vancomycin-resistant *Enterococcus* (VRE) is also very common in patients in the ICU and interpretation of urine cultures must be made with caution with this caveat in mind. It is important to distinguish between asymptomatic bacteriuria from a genuine urinary tract infection.

Clostridium Difficile

The frequent use of empiric systemic antibiotics puts many patients in the ICU at risk for *C difficile* infection. In patients with *C difficile* infection watery diarrhea is generally accompanied by marked leukocytosis; however some patients with toxic megacolon may also present with abdominal distension and reduced bowel sounds. The diagnosis can be confirmed with stool polymerase chain reaction (PCR) testing for *C difficile* toxin. If sigmoidoscopy is performed, pseudomembranes may also be noted, but stool assays are generally adequate for diagnosis. In addition to therapy with oral vancomycin or metronidazole, systemic antibiotics should be discontinued if possible. Stool transplant has emerged as a potentially useful therapy in particular for patients with refractory *C difficile* infection.

Central Nervous System Infections

Nosocomial meningitis is most commonly seen in hospitalized patients who have undergone neurosurgical procedures. When an infection is suspected in a febrile patient with an intracranial device, cerebrospinal fluid (CSF) should be obtained for analysis from the CSF reservoir. In patients with ventriculostomies who develop stupor or signs of meningitis, the catheter tip should be removed and cultured. CSF should be analyzed with Gram stain, cell count, protein, and glucose measurements. The most common organisms are *S aureus* and coagulase-negative staphylococci; however, Gram-negative organisms such as *Pseudomonas* and *Klebsiella* may also be responsible for CNS infections in this setting. Additional testing for tuberculosis, viral and fungal disease should be performed if there is a clinical suspicion of these less common organisms.

Postoperative Infections

Surgical site infections can be important causes of fever in patients recovering from recent surgery. These infections will often present with erythema and purulence at a surgical site and eventually may lead to dehiscence of the wound. Prompt surgical debridement is generally required for patients with this etiology of fever. Deeper infections may also occur in particular in patients with recent bowel surgery where intraluminal organisms can leak into the peritoneum and cause abscesses. Evaluation with CT or direct examination in the operating room may be necessary for patients with abdominal or pelvic collections. Drainage of collections and correction of anastomotic leaks are generally required in addition to appropriate antibiotic therapy.

Sinusitis

Sinusitis is a less frequent infectious cause of fever in the ICU. Most ICU patients have nasogastric tubes and endotracheal tubes which predispose them to nosocomial sinusitis. Other risk factors include facial fractures or nasal packing. The most common organisms causing nosocomial sinusitis are those that colonize the naso-opharynx. Gram-negative bacilli (especially *P aeruginosa*) constitute 60% of the bacteria isolated from nosocomial sinusitis. Gram-positive cocci such as *S aureus* are also common, and many infections are polymicrobial. Diagnosis may be made supported by imaging such as CT scan or confirmed with puncture and aspiration of the involved sinuses for culture and susceptibility if invasive testing is warranted.

NONINFECTIOUS CAUSES OF FEVER

A large number of noninfectious causes can cause tissue injury with inflammation and a febrile reaction (Table 38–2).

Postoperative Fever

Fever is common in the postoperative period during the first 48 hours and is due to release of endogenous pyrogens into the bloodstream. Usually fever this early in the postoperative period is noninfectious

TABLE 38–2 Noninfectious causes of fever in the ICU.

Drug fever
Neuroleptic malignant syndrome
Malignant hyperthermia
Acalculous cholecystitis
Intracranial hemorrhage
Early postoperative fever
Gout
Serotonin syndrome
Thromboembolic disease

Acute respiratory distress syndrome
Aspiration pneumonitis
Thyroid storm
Immune reconstitution inflammatory response
Stroke
Alcohol and drug withdrawal

in origin; however fever more than 96 hours after surgery is more likely to represent an infection and needs full evaluation. Although atelectasis is considered to be the most common cause of postoperative fever, clinical evidence regarding this association is scarce.

Medication Allergy

Numerous medications may be associated with an allergic response that includes fever. Any medication can cause fever due to hypersensitivity, which may manifest as fever alone to life-threatening hypersensitivity. Most common drugs known to cause fever are beta-lactam antibiotics, phenytoin, quinidine, procainamide, and methyldopa. Reactions to anti-epileptic medications such as phenytoin may also include elevated liver enzymes and skin eruptions but often fever is the only clinical manifestation of this problem. A high clinical suspicion is needed for diagnosing drug fever since there is nothing

characteristic about these fever patterns and they do not invariably occur immediately after drug administration. They may occur days after commencing a new medication, but a temporal relationship of the fever to starting and stopping the medication is supportive of this diagnosis.

Acalculous Cholecystitis

Acute acalculous cholecystitis is a condition of inflammation of the gall bladder in the absence of calculi. It is a disease with significant morbidity and mortality as it can lead to complications such as empyema of the gallbladder, gangrene, or perforation. A high index of suspicion is necessary, as it may be a difficult diagnosis to make in the sedated and intubated patient. The pathophysiology of this disorder is complex and involves hypoperfusion and biliary stasis. Risk factors include trauma, surgery, positive-pressure ventilation, total parenteral nutrition, sedation, immunosuppression, transfusion of blood products, and hypotension. Ultrasound or CT scan can be supportive of the diagnosis. As soon as the diagnosis is suspected, blood cultures should be drawn and broad-spectrum antibiotics commenced. Surgical intervention may be necessary, but may not be feasible in unstable patients.

Thromboembolic Disease and Hematoma

Deep venous thrombosis may be another noninfectious cause of fever. Patients with immobility, vascular injury, and underlying malignancies are at particular risk for thromboembolism. Large hematomas may also produce fevers and may be difficult to detect when they occur in the retroperitoneal space. Thrombotic thrombocytopenic purpura (TTP) is another syndrome associated with fever that also includes microvascular injury, platelet destruction, altered mental status, and renal injury.

Malignancies and Central fever

Certain malignancies such as lymphoma are associated with “B symptoms” such as weight loss, fevers, and sweats that may mimic infection. Brain injury or hemorrhage in the CNS may lead to hypothalamic dysfunction. Central fever and tumor fever are generally established as an etiology when infectious

etiologies and other noninfectious etiologies have been excluded.

EVALUATION OF THE FEBRILE ICU PATIENT

Initial Empiric Therapy

Once an infectious cause is suspected source control and early initiation of appropriate antimicrobial therapy are often the most important interventions for management. Infected catheters should be removed and abscesses should be drained. Empiric therapy should be based on the site of infection as well as local hospital epidemiology. Antimicrobials should be evaluated daily to reassess their need and potential de-escalation to avoid toxicity and emergence of resistant organisms. Positive cultures may help to narrow antibiotic coverage (Table 38–3).

Gram-Positive Organisms

S aureus, *Enterococcus*, and coagulase-negative staphylococci are among the common gram-positive pathogens involved in nosocomial ICU infections. Vancomycin can be included in the initial empiric regimen if these organisms are suspected. Linezolid or daptomycin may be used if there is a history of vancomycin-resistant *Enterococcus*, or vancomycin allergy. If methicillin-susceptible *S aureus* is isolated therapy should be switched to nafcillin or cefazolin.

Streptococcus pneumoniae and alpha-hemolytic streptococci (*Streptococcus viridans* group) are more common in community-acquired infections such as pneumonia or infective endocarditis. Empiric therapy for nosocomial pneumonia often includes broad-spectrum antibiotics with good levels of penetration in the lung tissue. Gram-positive coverage with vancomycin or linezolid is favored over

TABLE 38–3 Preliminary evaluation of the febrile ICU patient.

Blood cultures
Imaging studies
Urine cultures
Stool testing for <i>Clostridium difficile</i> (if diarrhea is present)
Sputum cultures/endotracheal aspirate
Peripheral blood smear evaluation

daptomycin due to surfactant binding of daptomycin. Broad-spectrum antibiotics with gram-negative activity may include cefepime or imipenem. In cases in which *Legionella* is suspected, fluoroquinolones or macrolides are appropriate.

Necrotizing fasciitis with group A *Streptococcus* may be seen in surgical site infections postoperatively and have a devastating outcome without surgical debridement and early appropriate antibiotic therapy. Penicillin G is usual drug of choice, as most streptococci are sensitive to penicillin. Clindamycin should be added for decreased toxin production effect for necrotizing fasciitis secondary to group A *Streptococcus*. Combination therapy may be necessary in certain infections such as enterococcal endocarditis which usually requires synergy with aminoglycoside in addition to vancomycin or penicillin.

Gram-Negative Organisms

Gram-negative organisms commonly encountered in an ICU-acquired infection include *P. aeruginosa*, *E. coli*, *K. pneumoniae*, *Acinetobacter* species, and *Stenotrophomonas*. Abdominal infections usually have mixed bacteriology including anaerobes. The emergence of multidrug-resistant gram-negative organisms has been a challenging problem in the ICUs in recent times. These organisms may produce carbapenemase enzymes that confer resistance to broad-spectrum agents such as imipenem and meropenem. When gram-negative infections are suspected, empiric antimicrobial agents should be chosen with knowledge of the local ICU resistance pattern.

Extended-spectrum beta-lactam penicillins such as piperacillin combined with a beta-lactamase inhibitor such as tazobactam have good activity against *Pseudomonas*, *E. coli*, *Proteus*, *Serratia*, *Klebsiella*, and most commonly encountered gram negatives. It also has excellent anaerobic activity comparable to metronidazole. Pharyngeal colonization with gram-negative bacilli rapidly develops in patients in the ICU, and initial therapy of nosocomial aspiration pneumonia requires the addition of an antipseudomonal penicillin, carbapenem, or cephalosporin. Higher

doses of piperacillin/tazobactam should be considered for serious infections due to *Pseudomonas*. Although traditionally aminoglycosides have been added for synergy or double coverage for *Pseudomonas*, there is little data to support this approach routinely.

Fungal Infections

Invasive and disseminated fungal infections are becoming increasingly common in the ICU. Risk factors for invasive fungal infections include broad-spectrum antibiotic use, immunosuppression, and use of total parenteral nutrition. Patients with lymphoproliferative disease, transplant patients, and advanced HIV disease are also at risk. Bloodstream infections with *Candida* remain the most commonly seen fungal infections and are usually susceptible to triazoles. *Candida krusei* and *Candida glabrata* may be resistant to fluconazole and voriconazole or caspofungin should be used when these organisms are suspected. Lipid preparations of amphotericin B are the initial drug of choice for empiric therapy of life-threatening, invasive, or systemic fungal infections including mucormycosis, cryptococcosis, histoplasmosis, and coccidioidomycosis.

Community-Acquired Infections in the ICU

Meenakshi M. Rana, MD

KEY POINTS

- 1 In community-acquired pneumonia (CAP), patients present with cough, fever, dyspnea, or pleuritic chest pain and an infiltrate is seen on chest x-ray; empirical antibiotics include an antipneumococcal beta-lactam and macrolide or respiratory fluoroquinolone for atypical coverage.
- 2 Diagnosis of urinary tract infection (UTI) requires symptoms including dysuria, urinary frequency, urgency, suprapubic pain, hematuria, or fever along with a positive urine culture.
- 3 Diagnosis and localization of intra-abdominal infection (IAI) can be challenging in the critically ill patient; history, physical examination along with laboratory examination, and imaging are critical.
- 4 Necrotizing skin and soft tissue infection is considered a surgical emergency and management includes debridement, resuscitation, and antimicrobial therapy.
- 5 Complications of infective endocarditis (IE) are often a reason for admission to the intensive care unit (ICU) and include valvular regurgitation, heart failure, splenic and renal infarcts, mycotic aneurysm, and neurologic complications such as cerebral emboli.

Community-acquired infections and concomitant sepsis are commonly a reason for admission to the ICU. In these infections, patients typically present with symptoms and signs prior to admission. The most common infections managed in the ICU are described below—CAP, UTIs, IAIs, necrotizing skin and soft tissue infections (NSTIs), and IE.

COMMUNITY-ACQUIRED PNEUMONIA

Introduction and Epidemiology

CAP is one of the most frequent causes of infection-related death in the United States. It occurs in approximately 4 million adults per year, accounting

for 1.1 million hospitalizations and 50,000 deaths per year. Of the 20% to 60% of patients who require hospital admission for CAP, anywhere between 10% and 22% may require critical care.¹ Mortality rates remain high despite advances in antibiotics and critical care.

Pathogenesis

The lower respiratory tract remains sterile because of a combination of pulmonary defense mechanisms that involve anatomic and mechanical barriers, and humoral and cell-mediated immunity. The development of CAP is therefore a result of either a defect in the host pulmonary defense system, an exposure to a virulent or large inoculum of microorganisms,

or a combination of these factors.² Certain risk factors for CAP have previously been described. These include increased age, male sex, malnutrition or poor dental hygiene, high alcohol consumption, smoking, immunosuppression including HIV, asplenia, and other underlying comorbidities.³

Microbiology

The most common etiology of CAP remains bacterial or viral; other fungal or parasitic organisms are isolated infrequently and are usually related to various geographic and host factors. Causes of bacterial CAP can be divided into typical or atypical organisms. The most common cause of CAP is *Streptococcus pneumoniae*; other typical bacterial pathogens include *Haemophilus influenzae*, *Moraxella catarrhalis*, *Staphylococcus aureus*, and gram-negative organisms such as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*, seen in patients with previous exposure to antimicrobials or structural lung disease. Community-associated methicillin-resistant *S. aureus* (CA-MRSA) as an etiology of CAP should be considered in the appropriate clinical situation, usually in patients presenting with cavitary pneumonia, lung necrosis, or concurrent influenza.⁴ Atypical organisms, such as *Mycoplasma pneumoniae*, *Chlamydophila* spp. (*Chlamydophila pneumoniae* and *Chlamydophila psittaci*), and *Legionella*, can often result in admission to the ICU. Viral etiologies should not be overlooked and include influenza and respiratory syncytial virus; other viruses such as parainfluenza, human metapneumovirus, and adenovirus should also be considered. Influenza specifically should be included in the differential of anyone presenting with CAP in the typical season, especially given that a significant number of patients can have concomitant bacterial infection. Other pathogens in the appropriate host include *Mycobacterium tuberculosis*, specifically in patients who are homeless, recently incarcerated, have HIV, or are from a country where tuberculosis is considered prevalent. Endemic fungi such as *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastocystis hominis* should be considered in patients from the appropriate geographic region. Immunocompromised hosts, such as solid organ transplant recipients, hematopoietic stem cell transplant recipients, patients with

HIV/AIDS, and patients on chemotherapy may be at risk for other opportunistic pathogens such as *Aspergillus*, *Cryptococcus*, and *Pneumocystis jirovecii* pneumonia.

Diagnosis

CAP is defined as acute infection of the lungs in patients who are not hospitalized or residents of long-term care facilities. Patients can present with symptoms of cough, fever, dyspnea, sputum production, and pleuritic chest pain. Other nonrespiratory symptoms may also be present. On physical examination, vital signs are notable for fever and associated tachycardia; hypotension is also present in severe CAP and concomitant septic shock. Tachypnea, the use of accessory muscles, or cyanosis and hypoxia are seen in respiratory compromise. Rales, bronchial breath sounds, and egophony are present on auscultation. On laboratory examination, leukocytosis with neutrophilic predominance is typically seen, although leukopenia can also occur in septic shock. Other signs of organ dysfunction such as acute kidney injury, hepatic dysfunction, lactic acidosis, and disseminated intravascular coagulation can also be seen with severe CAP and concomitant sepsis.

A chest radiograph should be performed and is critical to differentiating between upper respiratory and lower respiratory tract infection. Typically, a lobar infiltrate is present in bacterial pneumonia such as those seen in pneumococcal pneumonia; an interstitial pattern is typically seen with *Mycoplasma* and a bilateral mixed interstitial-alveolar pattern can be seen in viral pneumonia.² For patients hospitalized with suspected CAP but a negative chest x-ray, occasionally an infiltrate can be seen when the chest x-ray is repeated in 24 to 48 hours.⁵ Computed tomography (CT) of the chest is not routinely recommended given radiation exposure and expense; however, it may be useful in certain situations, such as nonresponse to initial therapy or in the immunocompromised host where certain infections such as *Aspergillus* and *M. tuberculosis* have a classic appearance.²

In patients admitted to the ICU, certain diagnostic tests are recommended by Infectious Diseases Society of America (IDSA)/American Thoracic Society (ATS) guidelines. All patients with severe CAP

should have blood cultures done to guide antibiotic therapy. In addition, urinary antigens for *Legionella pneumophila* and *S pneumoniae* should be performed. These may be especially useful in pneumococcal pneumonia when initial antibiotics have been given and the utility of a positive blood culture may be reduced. In *Legionella*, culture is less sensitive and urinary antigen testing is a useful tool for diagnosis, although only positive in serogroup 1. In addition, rapid antigen or PCR testing for viruses such as influenza should be performed in the appropriate clinical setting. If expectorated sputum of good quality with minimal oropharyngeal contamination can be obtained, it should be sent for Gram stain and culture. In intubated patients with severe CAP, endotracheal aspirates or bronchoscopy can be done to obtain respiratory samples for culture, with significantly more yield.⁵

Management

Severity Scoring Systems

For each patient being evaluated for pneumonia, the following 2 questions need to be asked—“Should the patient be hospitalized?” and if so, “Should the patient be admitted to the ICU?” Several scoring systems have been developed to assess severity of illness in order to identify patients with severe CAP. The first 2 tools, the Pneumonia Severity Index (PSI) and CURB-65, can aid in the diagnostic decision of whether or not to admit someone to the hospital. The PSI, which has been validated in several large studies, uses age, comorbidity, and vital signs to determine if the patient can be discharged and treated as an outpatient. The second tool, the British Thoracic Society CURB-65 system, uses fewer variables—confusion, urea, respiratory rate, blood pressure (BP), and age, to determine if patients can be treated as an outpatient or should be admitted.⁶

In addition, the IDSA/ATS has developed criteria to aid in identifying patients that would require admission to the ICU (Table 39–1). Any patient with one of the major criteria, either vasopressor use or respiratory failure requiring intubation and mechanical ventilation, require admission to the ICU. Patients with 3 of the minor criteria should also be considered for direct admission to an ICU.

TABLE 39–1 Criteria for severe community-acquired pneumonia.

Major Criteria	Minor Criteria
Septic shock requiring vasopressors	Respiratory rate ≥ 30 breaths/min
Acute respiratory failure requiring intubation and mechanical ventilation	PaO ₂ /FIO ₂ ratio ≤ 250
	Multilobar infiltrates
	Confusion/disorientation
	Uremia (BUN level ≥ 20 mg/dL)
	Leukopenia (WBC count < 4000 cells/mm ³)
	Thrombocytopenia (platelet count $< 100,000$ cells/mm ³)
	Hypothermia (core temperature $< 36^{\circ}\text{C}$)
	Hypotension requiring aggressive fluid resuscitation

BUN, blood urea nitrogen; WBC, white blood cell.

Validation studies support the use of the criteria in Table 39–1. Other scoring systems have been developed and include the SMART-COP, which aims to predict the need for respiratory or vasopressor support and the PIRO score, which aims to predict 28-day mortality.¹

Antimicrobial Therapy

The initial treatment for CAP is empiric therapy directed at the most common pathogens; specific risk factors based on the host as well as local hospital epidemiology should be taken into account when considering initial therapy. For patients admitted to the ICU with severe CAP, a beta-lactam for initial pneumococcal coverage and plus either azithromycin or a respiratory fluoroquinolone for atypical coverage is recommended. In patients with a severe penicillin allergy, a respiratory fluoroquinolone or aztreonam is recommended. If *Pseudomonas* is suspected based on risk factors such as structural lung disease in bronchiectasis or severe chronic

obstructive pulmonary disease (COPD) with frequent steroid or antibiotic use, then an antipseudomonal beta-lactam is recommended (ie, cefepime, piperacillin-tazobactam or a carbapenem).

Drug-resistant pneumococcus has been reported, with about 85% of isolates susceptible to penicillin and up to 30% of isolates demonstrating resistance to macrolides.¹ Respiratory fluoroquinolone resistance remains low in North America. In cases where CA-MRSA is suspected, such as necrotizing pneumonia or lung abscess, linezolid or vancomycin should be added.⁵ In one randomized control trial for nosocomial pneumonia, linezolid has been shown to have clinical superiority to vancomycin although there was no difference in 60-day mortality.⁷ It is unclear if this data can be generalized to patients with CAP. Ceftaroline, which has activity against MRSA in addition to other gram-positive and gram-negative pathogens, was approved for the treatment of CAP based on phase III trials which demonstrated noninferiority to ceftriaxone for the treatment of non-ICU hospitalized CAP.⁸ Telavancin, a new gram-positive agent, which has activity against MRSA, has also been approved for hospital-acquired pneumonia.⁹ Daptomycin is not effective in the treatment of MRSA pneumonia because it is inactivated by surfactant.

Antimicrobial therapy should be administered in the emergency department as quickly as possible in order to avoid delayed treatment, which has been associated with adverse outcomes. If a microbiological etiology is identified, treatment should be narrowed appropriately. In general, patients with CAP should be treated for at least 5 days,⁵ with the majority receiving around 7 to 10 days for severe CAP. Treatment can be continued with oral therapy once there has been clinical improvement. While studies on duration of therapy are generally limited, a randomized controlled trial looking at duration of therapy for ventilator-associated pneumonia (VAP) showed that 8 days of therapy were as effective as 15 days of therapy.¹⁰

URINARY TRACT INFECTIONS

Introduction and Epidemiology

UTI can be a challenging diagnosis and can present as various clinical syndromes ranging from acute

TABLE 39–2 Various urinary clinical syndromes.

Urinary Clinical Syndrome	
Asymptomatic bacteriuria	Significant bacteria in the urine in the absence of symptoms which is not treated
Uncomplicated urinary tract infection	Infection in a structurally and neurologically normal urinary tract
Complicated urinary tract infection	Infection in a urinary tract with functional or structural abnormalities, such as indwelling catheters and calculi
Acute pyelonephritis	Infection of the kidney and renal pelvis
Emphysematous pyelonephritis	Uncommon, severe, necrotizing infection of the kidney in which gas is seen in the renal parenchyma
Prostatitis	Infection or inflammation of the prostate

uncomplicated UTI to acute pyelonephritis, complicated UTI, and prostatitis (Table 39–2). Severe infection and sepsis usually occur in patients with complicated UTI who have functional or structural abnormalities of the urinary tract.¹¹

The urinary tract is a common source of sepsis in critically ill patients, ranging from 9% to 30% in different cohorts.¹² Risk factors typically include obstruction or hydronephrosis, and mucosal trauma including presence of indwelling catheters or manipulation of the urogenital tract with surgery. Other studies have shown that older age, female gender, and other comorbidities such as liver cirrhosis and diabetes are risk factors for severe infection.¹¹

Pathogenesis

UTIs occur through 3 different mechanisms by which bacteria invade the urinary tract—ascending, hematogenous, lymphatic. The ascending route accounts for the majority of UTIs in women and involves bacterial pathogens that colonize the vagina and periurethral area that ascend to the bladder, for example after vaginal

intercourse. The hematogenous route of infection involves seeding of the kidney in the setting of a bloodstream infection. The lymphatic route is uncommon and involves increased pressure in the bladder that directs lymphatic flow toward the kidney.¹³

Microbiology

The majority of UTIs are caused by *Escherichia coli*, isolated in 80% to 85% of episodes of community-acquired infections. In patients with complicated UTI who may have obstructive uropathy or neurogenic bladder, other Enterobacteriaceae such as *Klebsiella* or *Enterobacter* spp., *Pseudomonas* or *Proteus* are more likely to be isolated. Occasionally, gram-positive organisms such as *Enterococcus* or *Staphylococcus* as well as *Candida* spp. may be isolated, especially in patients with indwelling devices.¹¹ Renal abscesses have been described in patients with *S aureus* bacteremia and candidemia, presumably as a result of hematogenous infection. Antimicrobial resistance has been increasingly reported in community-acquired UTIs, specifically trimethoprim-sulfamethoxazole and fluoroquinolone resistance. The emergence of extended-spectrum beta-lactamase producing gram-negative organisms in community-acquired UTIs has also been described and renders limited treatment options.¹⁴

Diagnosis

The diagnosis of UTI can be challenging, especially in patients presenting with signs of sepsis. Patients should have symptoms of a UTI or history suggestive of a urinary source along with a positive urine culture. Symptoms of uncomplicated UTI include dysuria, urinary frequency, urgency, suprapubic pain, hematuria, or fever. Patients who present with symptoms of pyelonephritis may also have nausea, vomiting, flank pain, and concomitant bacteremia along with a positive urine culture. In addition, symptoms consistent with renal colic suggesting ureteral calculus or obstruction are also relevant in addition to history regarding recent urologic intervention, indwelling ureteral catheter, or presence of ureteral devices such as stents and nephrostomy tubes.¹¹

Physical examination should assess for costovertebral angle tenderness, hematuria, or presence of an indwelling device.¹¹ A clean catch urine sample should be sent for urinalysis and urine culture, and a positive urine culture is required for diagnosis of a urinary tract infection. Urine and blood cultures should be sent prior to administration of antimicrobial therapy, otherwise culture data may be falsely negative. If a patient has an indwelling urinary catheter in place, the urine sample should be sampled through the catheter port using aseptic technique or obtained from a freshly placed catheter, to avoid contamination of the urine sample. Typically, patients with a urinary source of infection have a single uropathogen isolated with greater than 10^5 colony-forming units/mL. A blood culture isolate with similar susceptibilities as the urine culture typically confirms a urinary source of infection. Urinalysis with pyuria alone is not helpful in making the diagnosis of symptomatic UTI as often times pyuria, accompanies asymptomatic bacteriuria, is present after an urologic procedure or in the presence of a urinary catheter. Imaging of the kidneys and bladder is helpful to identify structural abnormalities that may require source control, such as a perinephric abscess or emphysematous pyelonephritis that may require drainage or obstruction that may require decompression.¹

Management

Antimicrobial therapy and source control should guide the management of critically ill patients with sepsis due to UTI. For pyelonephritis requiring hospitalization, the IDSA guidelines recommend an intravenous fluoroquinolone with renal excretion such as levofloxacin or ciprofloxacin, an extended-spectrum cephalosporin (ceftriaxone, cefepime, ceftazidime), piperacillin-tazobactam, or a carbapenem.¹⁵ Local resistance data should be used to guide choice about initial therapy; for example, if fluoroquinolone resistance is known to be high, an extended-spectrum cephalosporin may be preferred. If there is a history of health care exposure or extended-spectrum beta-lactamase-producing organisms, then a carbapenem would be considered the drug of choice. Antibiotics should be administered rapidly, as this has previously been shown to improve outcomes in both severe UTI and sepsis.¹²

If a complicating factor in the urinary tract is identified, source control is warranted. In the management of an obstruction for example, decompression with percutaneous nephrostomy may be necessary; a large abscess may require drainage. In emphysematous pyelonephritis, initial percutaneous drainage is recommended with antimicrobial therapy, followed by nephrectomy if needed after the patient is stabilized.¹¹

Antibiotics should be narrowed based on urine culture and susceptibilities and can be transitioned to oral therapy once the patient has clinically improved. Traditionally, antibiotics for a 10- to 14-day course have been recommended for pyelonephritis and complicated UTI. However, recent data show that shorter courses of 7 days of treatment for acute pyelonephritis is equivalent to longer courses¹⁶ and the European Urology guidelines have recommended 3 to 5 days following defervescence and control of the complicating factor.¹¹ Treatment for acute bacterial prostatitis or abscess may require longer courses.

INTRA-ABDOMINAL INFECTIONS

Introduction and Epidemiology

IAIs represent a diverse group of infections and are a common source of sepsis in patients hospitalized in the ICU. Mortality rates range from 30% to greater than 50% in patients with increased severity of illness at presentation and organ dysfunction.¹⁷

Pathogenesis

IAIs refer to the invasion of enteric bacteria into the wall of a hollow viscus. There are 2 types of IAI—uncomplicated or complicated. An uncomplicated IAI refers to an inflammatory process confined to the wall of an abdominal organ. It can often times be managed with surgical resection and perioperative antibiotic prophylaxis alone, that is, cholecystitis and appendicitis.¹⁸ A complicated IAI extends beyond the organ through a perforated viscus, into the peritoneal cavity. It is associated with peritonitis and/or the formation of an abscess.¹⁹

Microbiology

The microbiology of the gastrointestinal (GI) tract is complex and contains a wide variety of gram-positive, gram-negative, and anaerobic organisms. In the oral cavity, gram-positive cocci harbor the mouth and oropharynx, but in the distal small intestine gram-negative organisms begin to predominate. Bacterial colony counts increase further down in the GI tract, with the largest colony counts being in the colon, with a predominance of anaerobic organisms. Most IAI are therefore usually polymicrobial in nature. Often times, all organisms may not be identified in the laboratory, especially anaerobes. The most common organism isolated in patients with community-acquired intra-abdominal infections is *E coli*, followed by other Enterobacteriaceae, such as *Klebsiella* and *Enterobacter*. Typically gram-positive organisms, such as *Enterococcus*, are seen in patients with nosocomial infection or in patients who are immunocompromised or have previously received broad-spectrum antibiotics or cephalosporins.²⁰ Anaerobic organisms most frequently isolated include members of the *Bacteroides* family. These patients who have a prolonged exposure to antimicrobial therapy often develop colonization and subsequent infection with other organisms such as *Pseudomonas* or *Candida* spp., and may develop infection with multidrug-resistant organisms such as multidrug-resistant *Acinetobacter* or vancomycin-resistant *Enterococcus faecium*.¹⁹

Clinical Presentation

The clinical presentation of IAI varies widely depending on location of the infection within the GI tract. In critically ill patients, the diagnosis can be especially difficult to make, given that history and physical examination may be limited in a sedated patient. Nonetheless, key history, physical examination, and laboratory and imaging findings together are essential to localizing intra-abdominal infection (Table 39–3).

Management

Management of IAIs is critical, especially in complicated IAI where morbidity and mortality are high in the ICU. Appropriate management involves both a

TABLE 39–3 Clinical manifestations of various intra-abdominal infections.^{21,22}

	Pathogenesis	History	Physical Examination	Diagnosis	Management Options
Appendicitis	Obstruction of the appendiceal lumen, resulting in ischemia and inflammation	Vague periumbilical pain that migrates to right lower quadrant	Tenderness with localized peritonitis Pain with flexion and internal rotation of Rhip (obturator sign) Pain with passive extension of Rhip (Psoas sign) Pain in RLQ with palpation of LLQ (Rovsing sign)	Leukocytosis with left shift CT scan with contrast	Appendectomy (laparoscopic vs open) Antibiotics (in cases with phlegmon) Percutaneous drainage and antibiotics in patients with appendiceal abscess
Cholecystitis	Calculous obstruction of the cystic duct or acalculous inflammation of the biliary tree in critically ill patients	RUQ pain, nausea, vomiting, fever; more subtle in acalculous presentation	RUQ tenderness with tenderness on inspiration (Murphy sign)	Leukocytosis, mild elevation of LFTs Ultrasound of RUQ shows thickened GB wall, pericholecystic fluid, sonographic Murphy sign	Cholecystectomy (laparoscopic or open) Percutaneous cholecystostomy as temporizing measure in poor surgical candidates
Cholangitis	Obstruction and stasis leading to bacteria ascending to the biliary tract	Charcot triad of fever, RUQ pain, jaundice	Fevers with rigors, RUQ tenderness, hypotension/sepsis	Increased total and direct bilirubin	Antibiotics and decompression of biliary system
Pancreatitis	Inflammation of the pancreas either mechanical (ie, gallstones, ERCP) or systemic (EtOH, medication-related, increased calcium, increased triglycerides)	Central upper abdominal pain, associated with nausea/vomiting, radiating to the back	Epigastric tenderness	Elevated serum amylase/lipase CT with contrast to assess for local complications or severity/necrosis	Fluid resuscitation/nutritional supplementation Systemic antibiotics and drainage/debridement in infected necrosis only
Diverticulitis	Acute inflammation of a diverticulum; can lead to perforation causing complicated disease	Pain in the lower abdomen; history of prior episodes	Pain in the LLQ or suprapubic tenderness	CT with contrast	Antibiotics and bowel rest for uncomplicated disease Drainage for abscess Sigmoid colectomy rare but may be needed in complicated disease

(Continued)

TABLE 39–3 Clinical manifestations of various intra-abdominal infections.^{21,22} (Continued)

	Pathogenesis	History	Physical Examination	Diagnosis	Management Options
Primary peritonitis	Not directly related to another intra-abdominal infection, ie, bacterial translocation in spontaneous bacterial peritonitis	Pain and fever, eg, in patients with cirrhosis/ascites	Dif use abdominal tenderness with rebound; may be more subtle in some patients, ie, patients on steroids	Elevated WBC count of ascitic fluid (> 250 PMNs) along with Gram stain and culture; typically monomicrobial	Antibiotics
Secondary peritonitis	Perforation of viscus in GI tract; may result in formation of abscess or walled-of cavity	Abdominal pain worse with movement, fever, nausea/vomiting	High fever, signs of sepsis Significant abdominal tenderness on palpation with rigidity of the abdominal wall produced by guarding, direct and referred rebound tenderness	Free air beneath the diaphragm on CXR; CT scan except in cases where RUQ source is suspected in which case ultrasound may be more helpful Typically polymicrobial	Antibiotics along with source control (see Table 39–5)

CT, computed tomography; CXR, chest x-ray; EtOH, ethyl alcohol; GI, gastrointestinal; LFT, liver function test; LLQ, left lower quadrant; PMN, polymorphonuclear; R, right; RLQ, right lower quadrant; RUQ, right upper quadrant; WBC, white blood cell.

combination of source control and appropriate antimicrobial therapy.

Source control refers to the concept of mechanical control of the source of infection, the elimination of ongoing contamination, and ultimately restoration of anatomy and function. In uncomplicated IAI, source control is sufficient to control infection and prevent development of complications, for example, an appendectomy. In complicated IAI, drainage or debridement along with a 5- to 7-day course of antimicrobials may be required. Drainage is used in the setting of an abscess and is commonly performed percutaneously using imaging. Surgical debridement is required in the setting of infected necrotic tissue.

Initial appropriate antimicrobial therapy is critical and has been shown to be associated with clinical outcome.²³ Empiric antimicrobial therapy should be directed against both aerobic and anaerobic gram-negative and gram-positive bacteria. Recommended empiric therapy includes a beta-lactam/beta-lactamase inhibitor such as piperacillin/tazobactam, a third- or fourth-generation cephalosporin with metronidazole, or a carbapenem.²⁴ Duration of therapy is 5 to 7 days if appropriate source control has been achieved.

NECROTIZING SKIN AND SOFT TISSUE INFECTIONS

Introduction and Epidemiology

NSTIs refer to the process of soft tissue necrosis secondary to toxin-secreting bacteria, and were first described by Hippocrates in 500 BC. During the Civil War, NSTI were further reported as “hospital gangrene” and noted to have high mortality rate. Since then, the pathogenesis of NSTI has been further described but is still associated with a high mortality rate anywhere from 25% to 35%.²⁵ Approximately 500 to 1500 cases have been described per year in the United States. Fournier gangrene is a variant of NSTI involving the penis, scrotum, or vulva. Risk factors such as diabetes mellitus, peripheral vascular disease, intravenous drug use, and other immunocompromising factors such as HIV and malignancy have been associated with NSTI.²⁵

Pathogenesis and Microbiology

NSTI is typically described as 2 types, type I and type II. Type I infections are monomicrobial and are caused by streptococci or clostridia species, and type

II infections are polymicrobial. Other organisms associated with NSTI in specific clinical situations include *Vibrio vulnificus*, *Aeromonas hydrophila*, and MRSA. Necrosis of the fascial and muscle layers is caused by exotoxin production of these pathogens and results in a rapid progression of infection and cytokine production causing septic shock.²⁶

Diagnosis

The diagnosis of NSTI can be challenging; initial skin findings can vary from skin discoloration or cellulitis to gangrene or necrosis. Symptoms progress quickly and are usually associated with ecchymosis, blisters or bullae, edema, crepitus, or necrosis. Pain may be out of proportion to what is seen on physical examination, and there may be a hard, wooden feel to the subcutaneous tissues. Systemic findings include fever and signs of sepsis such as tachycardia and hypotension. Laboratory examination is significant for a leukocytosis with left shift, electrolyte disturbances such as acidosis and elevated creatine kinase. Radiologic findings include soft tissue stranding or edema in the deep fascial layers and the presence of gas is highly specific. Frozen section biopsy can also be done to confirm diagnosis of NSTI. If clinical suspicion is high for NSTI, early surgical evaluation is indicated.²⁵

Management

NSTI is considered a surgical emergency and requires aggressive resuscitation along with surgical debridement and broad-spectrum antibiotics. Surgical debridement of all necrotic tissue is paramount and should be done as early as possible in order to improve outcome. Antimicrobial therapy serves as an adjunct to source control and should cover gram-positive, gram-negative aerobic and anaerobic organisms. Initially, empiric coverage includes a broad-spectrum beta-lactam such as piperacillin-tazobactam or carbapenem along with empiric vancomycin. In streptococcal toxic shock syndrome or necrotizing fasciitis caused by group A streptococci, therapy should be penicillin along with clindamycin, which is added for suppression of streptococcal toxin and cytokine production. Antimicrobial therapy should be continued until operative treatment is no longer needed and there has been clinical

improvement without fever for 42 to 78 hours.²⁷ Close monitoring in the ICU is important in order to provide supportive care with fluid resuscitation and optimal nutritional support.

INFECTIVE ENDOCARDITIS

Introduction and Epidemiology

IE remains relatively uncommon and affects about 10,000 to 15,000 people annually.²⁸ Men are affected more commonly and the median age of patients with IE is greater than 60. Common reasons for admission to the ICU include the development of congestive heart failure, septic shock, and neurologic deterioration.²⁹

Pathogenesis

The pathogenesis of IE involves initial damage to the endothelial surface of the valve, followed by platelet and fibrin deposition. This allows bacteria to subsequently adhere to the valve surface and produce disease at a lower inoculum.³⁰ Typical risk factors for IE include rheumatic heart disease, injection drug use, degenerative valve disease, prosthetic devices, and immunosuppression.²⁹

Microbiology

IE can be caused by several organisms, but is usually associated with *S aureus* and streptococci infection. *S aureus* is the most common cause of IE in the developed world, and is frequently associated with health care–associated infection. The streptococci make up a wide variety of organisms, but the viridans group streptococci are the most common pathogens associated with endocarditis, followed by *Enterococcus* and *Streptococcus bovis*. Coagulase-negative staphylococci, such as *Staphylococcus lugdunensis* have also increasingly been described. The HACEK organisms, *Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium* spp., *Eikenella corrodens*, and *Kingella*, have been associated with culture-negative endocarditis, although sterile blood cultures in the setting of endocarditis can be due to several different factors.³⁰ Lastly, organisms other than bacteria, such as fungi, can also be a rare cause of endocarditis, the most common of which is *Candida* spp.²⁹

Diagnosis

The diagnosis of IE involves pathologic diagnosis on examination of the valve or the presence of major or minor criteria as described by the modified Duke criteria (Table 39–4). Blood cultures are critical to the diagnosis and 3 sets should be obtained in the first 24 hours. If the patient received antibiotics previously, more blood cultures may be required. Echocardiography is central to the diagnosis of IE, and transesophageal echocardiography (TEE) is more sensitive than transthoracic echocardiography (TTE).

TABLE 39–4 Modified Duke criteria.

Definite infective endocarditis
Pathologic criteria <ul style="list-style-type: none">• Microorganisms demonstrated by culture or histologic examination of vegetation or intracardiac abscess or• Pathologic lesions: vegetation or intracardiac abscess confirmed by histologic examination
Clinical criteria <ul style="list-style-type: none">• 2 major criteria or• 1 major criterion and 3 minor criteria or• 5 minor criteria
Possible IE <ul style="list-style-type: none">• 1 major criterion and 1 minor criterion or• 3 minor criteria
Rejected <p>Firm alternative diagnosis explaining evidence of IE Resolution of IE syndrome with antibiotic therapy for ≤ 4 d No pathologic evidence of IE at surgery or autopsy with antibiotic therapy for ≤ 4 d</p>
Major criteria <p>Blood culture positive for IE—typical microorganisms from 2 separate blood cultures Echocardiography positive for IE</p>
Minor criteria
Predisposing heart condition or IDU
Fever greater than 38°C
Vascular phenomena, ie, arterial emboli, mycotic aneurysm, conjunctival or intracranial hemorrhage
Immunologic phenomena, ie, glomerulonephritis, Osler nodes, Roth spots
Microbiological evidence not meeting criteria above or serologic evidence of active infection

A good-quality TTE with a low clinical suspicion usually excludes the diagnosis of IE. However in cases where there is high clinical suspicion and TTE is negative or a suboptimal examination, TEE may be required. Occasionally repeat TEE after 7 to 10 days is needed to reassess for a vegetation in the setting of an initial negative examination.

Clinical Manifestations

Patients present with fever and other nonspecific symptoms, such as anorexia, weight loss, and malaise, especially in subacute cases. On examination, an audible heart murmur is heard about 85% of the time.³⁰ Other findings on physical examination include splinter hemorrhages (linear streaks in the fingernails or toenails), conjunctival petechiae, Osler nodes (small, painful nodular lesions on pads of fingers or toes), Janeway lesions (macular, painless plaques seen on palms or soles), and Roth spots (retinal lesions surrounded by hemorrhage).

The most common complication of IE is severe valvular regurgitation or heart failure. Major embolic phenomena are the second most common complication and may reflect the initial clinical presentation. Splenic emboli with infarction may cause left upper quadrant abdominal pain and renal infarction may present with hematuria. Renal abscess or glomerulonephritis may also be seen in the setting of IE. Mycotic aneurysms, or direct bacterial invasion or immune complex deposition in the arterial wall, can be seen in cerebral vessels or in the abdominal aorta. Neurologic complications are a common cause of initial ICU admission and include ischemic cerebrovascular accident (CVA), cerebral hemorrhage, or brain abscess. Right-sided IE may present as pulmonary embolism or infarction.³⁰ Anemia is almost always seen and erythrocyte sedimentation rate (ESR) is usually elevated, although laboratory parameters are not diagnostic.²⁹

Management

American Heart Association (AHA) and IDSA guidelines include recommended pathogen-guided antimicrobial therapy for IE, as listed in Table 39–5.³¹ Surgical indications in IE include heart failure not responsive to medical therapy, severe aortic or mitral regurgitation, endocarditis due to highly resistant

TABLE 39–5 Management of native-valve endocarditis.

Organism	Susceptibility Testing	Treatment Options	Duration	Comments
Staphylococcus aureus	Oxacillin-susceptible	Nafcillin	6 wk	Addition of gentamicin no longer routinely recommended given nephrotoxicity ³²
		Cefazolin	6 wk	
	Oxacillin-resistant	Vancomycin	6 wk	Approved for right-sided endocarditis
		Daptomycin	6 wk	
Streptococcal IE (ie, viridans group Streptococcus or Streptococcus bovis)	Penicillin highly susceptible (MIC < 0.12)	Penicillin (PCN)	4 wk	Selected patients without intracardiac or extracardiac complications and no preexisting renal disease may be given shorter course of combination therapy ²⁸
		Ceftriaxone (CTX)	4 wk	
		PCN/CTX plus gentamicin	2 wk	
Streptococcal IE	Penicillin relatively resistant (MIC 0.12-0.5)	PCN/CTX plus gentamicin	4 wk of PCN/CTX 2 wk of gentamicin	
Streptococcal IE	Penicillin resistant (MIC > 0.5)	Same as Enterococcus		
Enterococcus	Penicillin susceptible	Ampicillin or penicillin plus gentamicin (if susceptible)	4-6 wk	No randomized control trials comparing treatments in enterococcal IE; recent data suggest shorter duration of gentamicin may be as effective with less nephrotoxicity ³³
	Penicillin susceptible	Ampicillin plus ceftriaxone	4-6 wk	Recent data suggest this may be an alternative to combined beta-lactam/aminoglycoside therapy, especially in the setting of gentamicin resistance ³³
	Penicillin resistance	Vancomycin plus gentamicin	6 wk	
	Penicillin resistance/ vancomycin resistance	Daptomycin or linezolid	6 wk	Should be done in consultation with infectious disease specialist given side effects associated with prolonged therapy and cardiac valve replacement may be necessary ³¹
HACEK		Ceftriaxone	4 wk	
		Ampicillin-sulbactam	4 wk	
		Ciprofloxacin	4 wk	

organisms or persistent bacteremia, perivalvular infection with abscess, recurrent emboli or persistent vegetations, and large, mobile vegetations greater than 10 mm.²⁸

Health Care–Associated Infections

Subani Chandra, MD and David Chong, MD

KEY POINTS

- 1 Health care–associated infections (HCAs) contribute significantly to morbidity and mortality, and health care costs.
- 2 The most frequent HAIs are catheter-related bloodstream infections (CRBSIs), ventilator-associated pneumonias (VAPs), infections with *Clostridium difficile*, surgical site infections (SSIs), and catheter-associated urinary tract infections (CAUTIs).
- 3 Major preventive strategies to reduce CRBSIs include optimal catheter site selection; proper hand hygiene; maximal barrier precautions at the time of insertion; chlorhexidine skin antisepsis, use of chlorhexidine-impregnated dressings, or use of antiseptic or antimicrobial-coated catheters; tunneled insertion; catheter site care and limited manipulation of the catheter; and daily review of line necessity and prompt removal of unnecessary lines.
- 4 The most common causes for VAPs are aerobic gram-negative bacilli such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Acinetobacter* species and less commonly gram-positive organisms such as *Staphylococcus aureus*.
- 5 *C difficile* can cause a wide range of disease from asymptomatic infection in a silent carrier state to fulminant disease associated with severe sepsis and death.
- 6 Essential elements of the SSI bundle include appropriate use of prophylactic antibiotics; appropriate hair removal, controlled postoperative serum glucose in patients after cardiac surgery, and immediate postoperative normothermia in patients with colorectal surgery.
- 7 The single most significant risk factor for a CAUTI is the prolonged use of the urinary catheter.

INTRODUCTION

HCAs, particularly those acquired in a critical care setting contribute significantly to morbidity and mortality, and health care costs. Critically ill patients have more comorbid diagnoses and higher severity of acute illness making them particularly susceptible to new infections while hospitalized. Indwelling catheters and increasing prevalence of multidrug-resistant (MDR) pathogens add to the risk and

negative consequences of HCAs. One in 20 patients acquires a HCAI while receiving medical care.¹ The most frequent HCAs include bloodstream infections (BSIs), VAPs, infections with *C difficile*, SSIs, and CAUTIs.

Bloodstream Infections

BSIs or bacteremias remain common in hospitalized patients both within the intensive care units (ICUs)

and in hospital wards. About 90% of these BSIs are associated with a catheter in the bloodstream, usually a central line.² CRBSIs are considered a preventable cause of morbidity and mortality and are a target of interventions aimed at improving quality of health care and cost-effectiveness.

Risk Factors and Microbiology

Central lines are at risk for infection both during the process of insertion and subsequent access and maintenance. Factors associated with a lower incidence of CRBSIs include the following:

- Optimal catheter site selection (subclavian vs internal jugular, or femoral veins)
- Use of proper hand hygiene
- Maximal barrier precautions at the time of insertion
- Chlorhexidine skin antisepsis, use of chlorhexidine-impregnated dressings, or use of catheters coated with antiseptic or antimicrobials
- Tunneled insertion
- Catheter site care and limited manipulation of the catheter
- Daily review of line necessity and prompt removal of unnecessary lines

Gram-positive aerobes are the most frequently isolated pathogens from the bloodstream of hospitalized patients. Coagulase-negative staphylococci and *S aureus* account for just over half of all nosocomial bacteremias (51%). *Candida* species and enterococci were each responsible for 9% of BSIs. Gram-negative bacteria, including many MDR species, accounted for most of the remainder.³

Certain patient populations are at increased risk of CRBSIs and may have greater susceptibility to microbial pathogens not commonly responsible for infections otherwise. Patients receiving intravenous hyperalimentation or high concentrations of glucose via a central line are particularly susceptible to fungal infections especially *Candida* species. Gram-positive aerobes are the most commonly isolated pathogens from the bloodstream of patients who receive hemodialysis. Immunocompromised hosts, especially those who are neutropenic or receiving chemotherapy may translocate microbes from their gut into the

bloodstream and therefore have a disproportionately high rate of infection with gram-negative bacilli. Burn victims are particularly susceptible to infections due to *Pseudomonas* species.

Diagnosis

The diagnosis of CRBSI is based on clinical criteria and microbiological confirmation. The clinical symptoms and signs of CRBSI can be protean and need not include typical indicators of infection such as fever, especially in critically ill patients. A high degree of suspicion should be maintained in a patient with a central line and clinical changes. Positive blood cultures in the absence of other identifiable source of infection suggest a CRBSI. Proper specimen collection prior to initiation of antimicrobial therapy and repeat sampling can help increase the yield of microbial cultures. Positive cultures taken from a peripheral site have the highest specificity; cultures drawn from the catheter have a high false-positive rate but excellent negative predictive value.

Treatment

Once CRBSI is confirmed, the treatment is focused on catheter management and antimicrobial treatment. In critically ill patients with a CRBSI and signs of sepsis or hemodynamic instability, the catheter should be removed promptly. Additionally, clinical practice guidelines recommend catheter removal if there is endocarditis or persistent bacteremia after 72 hours of appropriate antibiotic treatment, or fungemia.⁴ Catheter removal is also recommended in cases of infection with most organisms encountered in critical care settings: *S aureus*, gram-negative bacilli (including *Pseudomonas*), mycobacteria, and low-virulence organisms such as *Bacillus* species or *Propionibacterium*.

Infrequently, salvage of long-term catheters with systemic antimicrobial therapy with or without an antibiotic lock may be attempted if none of the criteria for removal are met. Similarly, in a patient without sepsis or hemodynamic instability, a catheter may be exchanged over a guidewire if the risks of catheter reinsertion are considered to be unacceptably high. However, it is important to note that the success rate of these strategies is low and unpredictable and the data supporting catheter exchange are sparse and present only in small, uncontrolled studies.

Empiric antimicrobial therapy for CRBSIs usually includes antibiotics to cover resistant gram-positive organisms including *S aureus*, such as vancomycin. Additionally, empiric therapy should be tailored to the patient, based on host risk factors and susceptibility to certain infections as discussed earlier. Antimicrobial therapy should be reassessed and narrowed based on microbiological profile as soon as culture results are available.

Typical duration of antimicrobial therapy in uncomplicated CRBSI is 10 to 14 days from the first day blood cultures turned negative. In suspected or confirmed endocarditis, treatment is usually continued for 4 to 6 weeks.

Follow-Up and Outcomes

After initiation of antimicrobial therapy, patients with BSIs should be followed closely and monitored with surveillance cultures until the bacteremia or fungemia resolves. Persistently positive cultures or lack of clinical improvement should prompt investigation of the causes of treatment failure: inappropriate antimicrobial therapy, failure to remove the catheter, or development of an associated complication such as a persistent secondary source of infection or a septic focus, endocarditis, or suppurative thrombophlebitis.

CRBSIs are associated with increased hospital length of stay and costs and have an associated mortality of 25%.⁵ Every effort should be made to prevent CRBSIs.

Pneumonia

Definitions

Hospital-acquired pneumonia (HAP) is defined as a pneumonia that occurs 48 hours or more after hospital admission that did not exist at the time of admission. VAP is defined as a pneumonia that occurs 48 hours after intubation and institution of mechanical ventilation. Health care–associated pneumonia (HCAP) includes pneumonia that occurs within 48 hours of hospital admission in patients who were hospitalized for 2 or more days within 90 days of the infection, or resided in a nursing home or long-term care facility, or received recent intravenous antibiotic therapy, chemotherapy or wound care within the past 30 days, or attended a hospital or hemodialysis clinic.

Ventilator-associated event (VAE) is a recent surveillance definition developed by the Centers for Disease Control and Prevention (CDC) to create a more objective and systematic way of measuring VAPs. VAEs may not represent true clinical VAPs. In the VAE algorithm there are sequential tiers. The first tier is ventilator-associated condition (VAC) defined as an increase in the fraction of inspired oxygen (FIO_2) of 0.20 for 2 or more days or an increase in positive end-expiratory pressure (PEEP) of greater than or equal to 3 cm H_2O for 2 days after 2 or more days of stable or decreasing daily minimal values. Tier two is infection-related ventilator-associated condition (IVAC) which includes VAC plus a temperature greater than 38°C or less than 36°C or white blood cell count greater than or equal to 12,000 or less than or equal to 4000 cells/ mm^3 , and initiation of a new antimicrobial agent that is continued for 4 or more days. The third tier is for patients that meet the IVAC definition and have purulent secretions (defined as ≥ 25 neutrophils and ≤ 10 squamous epithelial cells per low power field) or have a positive sputum or other specimen culture, for a designation of possible VAP. Qualification as a probable VAP does not allow use of sputum, instead the patient must have purulent secretions and a positive quantitative or semiquantitative aspirate or lavage or biopsy, or in the absence of purulent secretions, a positive pleural culture, lung pathology, or diagnostic serology for virus or *Legionella*.⁶ Note that the CDC VAE definitions exclude chest radiographs due to their subjectivity and variability in their technique, interpretation, and reporting.

Epidemiology

HAP is the second most common nosocomial infection in the United States and accounts for up to 16% of all hospital-acquired infections (HAIs) and up to 27% of HAIs in the ICU.⁷ HAPs can increase hospital stays up to 9 days and cost as much as \$40,000 per patient. VAP can occur in 9% to 26% of all intubated patients. Attributable mortality ranges from 0% to 50%. In 2002, an estimated 250,000 HAPs developed in US hospitals and 36,000 of these were associated with deaths.⁶ Major risk factors for HAP include age more than 70, underlying chronic lung disease, immunosuppression, prolonged intubation, enteral feeding, and prior thoracoabdominal surgery.

Pathogenesis

The common causes of VAPs are microaspiration of oropharyngeal organisms, inhalation of aerosols containing bacteria, infected biofilm in the endotracheal tube with subsequent embolization to the distal airways, and less commonly hematogenous spread via infected intravenous catheters and gut translocation. Aspiration is the most common cause of HAP and VAP in hospitalized patients with risks that are often increased due to intubation, sedation, and bacterial colonization of the oropharynx with gram-negative organisms. Intubated patients are at the highest risk for VAP due to the common use of sedation, reduced cough, and the leakage of oropharyngeal contents and organisms around the high volume, low-pressure cuffs of the endotracheal tube, as well as the formation of a biofilm and subsequent colonization with bacteria. The risk of pneumonia increases each day the patient is intubated and can be as high as 3% for the first 5 days, 2% from days 5 to 10, and 1% per day afterward. The most common causes for HAP/HCAP/VAP are aerobic gram-negative bacilli such as *P aeruginosa*, *K pneumoniae*, and *Acinetobacter* species and less commonly gram-positive organisms such as *S aureus*. Anaerobes are an uncommon cause of VAP. Early-onset VAP occurs within 96 hours of admission, is usually caused by antibiotic-sensitive bacteria, and has a more favorable prognosis. Late-onset VAP occurs after 96 of ICU admission and is commonly caused by MDR pathogens. Risk factors for MDR pathogens include immunosuppression, prior antibiotic use, HCAP risk factors, and high frequency of resistance in the community or hospital unit.

Diagnosis

The diagnosis of HAP or VAP can be challenging. The clinical approach includes a chest radiograph that shows a new infiltrate plus at least 2 of the following features: temperature greater than 38°C or less than 36°C, leukocytosis greater than 12,000 or leukopenia less than 4000 cells/mm³, and purulent secretions. As opposed to the VAE surveillance criteria, chest radiographs are clinically recommended to assess for the severity of pneumonia (such as multilobar involvement), and to detect complications like pleural effusion, cavitation, and pneumothorax. Given the high sensitivity but very low specificity of

this approach as well as the emergence of more MDR pathogens and the polymicrobial nature of HAPs and VAPs, the search for the causative organism(s) should be attempted with blood cultures and semi-quantitative sputum cultures prior to the start of empiric antibiotics. Furthermore, if available and logistically possible the ideal approach is a quantitative sampling of the lower respiratory tract with an endotracheal aspirate, bronchoalveolar lavage (BAL), or protected brush sampling. The diagnostic thresholds for BAL are 10⁴ to 10⁵ CFU/mL, and for protected brush sample 10³ CFU/mL. A diagnostic thoracentesis should be performed if the pleural effusion is large or if the patient appears toxic. The Clinical Pulmonary Infection Score (CPIS) includes temperature, white blood cell count, tracheal secretions, oxygenation (PaO₂/FiO₂), chest radiography, and microbiological data. A score of greater than or equal to 6 suggests pneumonia and a score less than 6 suggests that antibiotics can be safely discontinued. However, due to the overall low sensitivity and specificity of the CPIS it has not been widely used clinically to diagnose VAP. Procalcitonin (PCT) is a biomarker that has been studied in hospitalized as well as outpatients to help diagnose sepsis and pneumonia. It has shown to have a high specificity for bacterial infections rather than for viral infections. Unfortunately, PCT is elevated in many noninfectious inflammatory disorders such as burns, major surgery, trauma, and pancreatitis, as well as sepsis from any etiology. The use of PCT in the critically ill has yet to be fully realized. There is data suggesting that a very low or a significant decrease in PCT levels can allow for safe and earlier discontinuation of antibiotics.

Treatment

The key decision in the initial empiric antimicrobial treatment of patients with VAP or HAP rests on whether the patient has risk factors for MDR pathogens. If patients have the previously mentioned risk factors or if they have been intubated or in the hospital for more than 96 hours, coverage for MDR pathogens is required. Several studies have showed an increase in mortality by 2- to 3-fold if inappropriate or delayed (> 24 hours) antibiotics are given. The American Thoracic Society/Infectious Diseases Society of America guidelines published in 2005 can

TABLE 40–1 2005 ATS/IDSA guidelines.

Empiric Antibiotic Treatment in Patients With no Known Risk Factors for MDR Pathogens	
Potential Pathogens	Antibiotics
Streptococcus pneumoniae Haemophilus influenzae Methicillin-sensitive Staphylococcus aureus Antibiotic sensitive enteric GNB Escherichia coli Klebsiella pneumoniae Enterobacter spp Proteus spp Serratia marcescens	Ceftriaxone 2 g daily OR Ampicillin-sulbactam 3 g every 6 hours OR Levofloxacin 750 mg daily OR Moxifloxacin 400 mg daily OR Ertapenem 1 g daily
Empiric Antibiotic Treatment in Patients Known Risk Factors for MDR Pathogens	
Potential MDR Pathogens Gram Negatives	Combination Antibiotics Therapy*
Pseudomonas aeruginosa Acinetobacter baumannii Antibiotic resistant enteric GNB Escherichia coli Klebsiella pneumoniae Enterobacter spp Proteus spp Serratia marcescens	Beta-lactam/beta-lactamase inhibitor Piperacillin/tazobactam 4.5 g every 6 hours OR Antipseudomonal cephalosporins Ceftazidime 2 g every 8 hours Cefepime 2 g every 8 hours OR Antipseudomonal carbapenems Imipinem 500 mg every 8 hours Meropenem 1 g every 8 hours PLUS Antipseudomonal fluoroquinolone Levofloxacin 750 mg daily Moxifloxacin 400 mg daily Ciprofloxacin 400 mg every 8 hours OR Aminoglycosides† Gentamicin 7 mg/kg daily Tobramycin 7 mg/kg daily Amikacin 20 mg/kg daily
Gram positives Methicillin-resistant Staphylococcus aureus	PLUS Linezolid 600 mg every 12 hours Vancomycin 15-20 mg/kg every 12 hours‡

*Dosages based on normal renal and hepatic function.
†Trough levels for gentamicin and tobramycin should be < 1 µg/ml, and for amikacin, they should be < 4-5 µg/ml.
‡Trough levels for vancomycin should be 15-20 µg/ml.
Data from American Thoracic Society; Infectious Diseases Society of America: Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia, Am J Respir Crit Care Med 2005 Feb 15;171(4):388-416.

help with the initial choice of antimicrobial agents and are shown in [Table 40–1](#).

Prevention

General strategies that have been found to influence the risk of VAP include active surveillance for VAP. The Institute for Healthcare Improvement (IHI) endorses the ventilator bundle checklist. Although not all the elements are aimed at VAP prevention, it represents the best practices for patients on

mechanical ventilation. The elements include keeping the head of the bed elevated 30° to 45°, daily sedation interruption and assessment of readiness to extubate, daily oral care with chlorhexidine, peptic ulcer disease prophylaxis, and deep venous thrombosis prophylaxis. Another essential element is the emphasis on adherence to the hand hygiene guidelines. Other strategies that appear helpful include using standardized weaning protocols, using non-invasive positive pressure ventilation (NIPPV)

whenever possible, educating the staff about VAP prevention, using subglottic drainage (shown to decrease early-onset VAP),⁸ changing the ventilator circuit only when visibly soiled or malfunctioning, using a closed in-line suctioning system, and avoiding nasotracheal intubation (which may result in sinusitis that will increase the risk of VAP). However, the most important element of all is the implementation strategy. For such a strategy to be effective it is important to have complete buy-in and accountability of the senior clinical and administrative leadership on the importance of VAP prevention, education of the staff, monitoring of practice, and feedback to all staff on the outcomes, risk factors, and local epidemiology. It is essential to measure the occurrence of VAP as well as compliance with performance measures such as adherence to the ventilator bundle elements and hand hygiene.⁹ A checklist is not enough; there must be cultural (adaptive) change to effect true change in practice.

Infection With *C. difficile*

C. difficile is the most commonly reported nosocomial pathogen and causes about 12% of HCAs.¹⁰ The spectrum of disease caused by *C. difficile* can range from an asymptomatic carrier state to varying severity of colitis with diarrhea. Both the incidence and severity of *C. difficile* infections (CDIs) have increased dramatically since the late 1990s. In North America, the overall incidence of CDI went up 5-fold and the attributable mortality rate has increased 4-fold. Those above the age of 65 are particularly susceptible and the incidence of CDI in the elderly increased 8-fold.¹¹ In the United States alone, an estimated 500,000 cases of CDI occur annually and about 15,000 to 20,000 patients die from CDI each year.⁵

Risk Factors

The single greatest risk factor for CDI is antibiotic use. Antibiotics disrupt the natural flora in the gut, and this along with high resistance of *C. difficile* to the most commonly used antibiotic agents allows *C. difficile* to proliferate and CDI to occur. The risk of CDI is higher with the use of multiple antibiotics, broader-spectrum agents, and longer duration of therapy. Almost all antibiotics have been associated with CDI but the risk is highest with clindamycin, broad-spectrum cephalosporins, and fluoroquinolones.

Notably, fluoroquinolone resistance of the NAP1/B1/027 strain is believed to be an important factor in the increased virulence of *C. difficile*.

Patients above the age of 65 are at increased risk of severe CDI. Use of gastric acid suppressants (proton pump inhibitors and H₂ receptor blockers) is also a possible risk factor for CDI. Immunosuppressive agents such as methotrexate and the presence of chronic inflammatory bowel disease have also been associated with CDI. Hospitalization or residence in a long-term care facility bring together multiple risk factors for CDI and are therefore responsible for almost all the cases.

Spectrum of Disease

C. difficile can cause a wide range of disease in patients: at one end is asymptomatic infection in a silent carrier state, and at the other end, fulminant disease associated with severe sepsis and death.

Asymptomatic carriage: About 20% to 30% of hospitalized patients and 50% of residents of long-term care facilities are silent carriers of *C. difficile*. They have no symptoms but serve as a reservoir of infection and can play an important role in transmission of *C. difficile*.¹²

***C. difficile* diarrhea (CDAD):** This presents as antibiotic-associated diarrhea and is one of the most frequent manifestations of CDI. Systemic symptoms such as fever and leukocytosis are less frequent.

***C. difficile* colitis:** This is a more severe form of CDAD and presents with high-volume watery, foul-smelling diarrhea with fever and leukocytosis. Pseudomembranes are not seen.

Pseudomembranous colitis: Diarrhea is more severe and may progress to a protein-losing enteropathy. Fever and leukocytosis are common. Pseudomembranes are seen on sigmoidoscopy.

Fulminant colitis: This is the most serious, life-threatening form of CDI occurring in about 3% of patients. Prolonged ileus, toxic megacolon, colonic perforation, severe sepsis, and death may occur. Diarrhea may be much less prominent due to ileus.

Diagnosis

CDI should be suspected in any patient with diarrhea and antibiotic exposure or another risk factor.

Different methods for laboratory confirmation of CDI are available. A cytotoxin assay that detects the cell toxicity of toxin B is considered the gold standard with a sensitivity of 67% to 100% and a specificity of 85% to 100%.¹³ It is a tissue culture test and results can take up to 3 days.

An enzyme-linked immunosorbent assay (ELISA) is also available. While the ELISA is rapid and can provide results within a few hours, it has a relatively low sensitivity (75%–85%) but a high specificity (95%–100%); thus false-negative results are not infrequent.¹³ *C. difficile* can be isolated in anaerobic stool culture but cannot distinguish between toxigenic and nontoxigenic strains. Molecular methods such as polymerase chain reaction (PCR) are rapid and sensitive tests for detection of *C. difficile* that are being increasingly used.

Treatment

First-line treatment is based on the severity of CDI. Oral metronidazole is the initial treatment recommended for mild and moderate CDI. Oral vancomycin is superior to metronidazole for treatment for severe CDI. For patients with the most severe form of disease, or complications such as ileus or toxic megacolon, current guidelines recommend treatment with a combination of oral vancomycin and intravenous metronidazole. Surgery with colectomy may be needed as a lifesaving measure in extreme cases. Many newer approaches and antimicrobial agents for the treatment of CDI are under development but none are recommended for routine use at this time. Studies of probiotics aimed at restoring normal gut flora are inconclusive for treatment of CDI. Supportive care and management of fluid status and electrolytes are important adjuncts to treatment of CDI. Antibiotics that may have contributed to the development of CDI should be stopped as soon as possible.

Recurrence

Twenty percent of patients with one episode of CDI develop recurrent infection and 60% of those who have had 2 episodes will develop recurrence. About half of the recurrences are due to new infections and not relapses per se. Persistence of risk factors for CDI and depletion of normal gut flora contribute to recurrence. The first recurrence is treated in a

manner similar to the initial episode with metronidazole and/or vancomycin based on the severity of illness. Further recurrences may benefit from a prolonged taper of oral vancomycin. Fecal transplant can help restore normal flora and may be effective in the management of recurrent CDI.

Prevention

Prevention of CDI involves measures targeted at the individual patient and other interventions designed to prevent the spread of *C. difficile* spores within the hospital environment. Judicious use of antibiotics and avoidance of high-risk agents can help reduce the incidence of CDI. Acid suppressants should only be used when clearly indicated.

On a broader scale, containment of *C. difficile* infections within hospital and health care facilities is essential to prevent spread between patients. *C. difficile* is transmitted when spores infect patients via the fecal-oral route. The spores can be transferred between patients via equipment or the hands of health care providers. Rapid and reliable detection of CDI is critical to early isolation of infected patients. Contact precautions with the use of gowns and gloves for all visitors and health care providers should be strictly enforced. Hand washing with soap and water is essential after caring for a patient with CDI since commonly used antimicrobial hand gels are ineffective against spores of *C. difficile*. These spores are hardy and resistant to desiccation, chemicals, and extremes of temperatures. They can survive on surfaces for months. Environmental decontamination should be diligently performed to prevent transmission of CDI.

Surgical Site Infections

SSIs are a very common cause of HCAs. From 2007 to 2010, SSIs accounted for approximately 23% of all HCAs.¹⁴ More than 5% of all surgical patients acquire an SSI and many (40%–60%) are preventable.¹⁵ SSIs are classified as being either incisional or organ/space infections. Incisional SSIs are further divided into those involving only skin and subcutaneous tissue (superficial incisional SSI) and those involving deeper soft tissues of the incision (deep incisional SSI). Organ/space SSIs involve any part of the anatomy that was opened or manipulated during an operation, other than incised body wall layers.

Microbiology

S aureus, coagulase-negative staphylococci, *Enterococcus* spp., and *Escherichia coli* remain the most frequently isolated pathogens. An increasing proportion of SSIs are caused by MDR pathogens, such as methicillin-resistant *S aureus* (MRSA), or by *Candida albicans*.

Pathogenesis

Microbial contamination of the surgical site is a necessary precursor of SSI. The risk of SSI can be conceptualized according to the following relationship¹⁶:

$$\frac{\text{Dose of bacterial contamination} \times \text{virulence}}{\text{Resistance of the host patient}} \\ = \text{Risk of surgical site infection}$$

Quantitatively, if a surgical site is contaminated with greater than 10^5 microorganisms per gram of tissue, the risk of SSI is markedly increased. However, the dose of contaminating microorganisms required to produce infection may be much lower when foreign material is present at the site (ie, 100 staphylococci per gram of tissue introduced on silk sutures).

Outcomes

SSIs are associated with considerable morbidity with over one-third of postoperative deaths related, at least in part, to SSIs. SSIs can double the length of time a patient stays in the hospital and thereby can increase the cost of health care.

Prevention

Essential processes for prevention of SSIs are core measures in the Surgical Care Improvement Project: Hospital Compare Hospital Quality Initiatives.¹⁷ The essential elements of the SSI bundle¹⁸ are appropriate use of prophylactic antibiotics; appropriate hair removal, controlled postoperative serum glucose in patients after cardiac surgery, and immediate postoperative normothermia in patients with colorectal surgery.

It is important to standardize the administration process of delivering prophylaxis so that antibiotics can consistently be given within 1 hour prior to incision. Overuse, underuse, improper timing,

and misuse of antibiotics occurs in 25% to 50% of operations. A large number of hospitalized patients develop infections caused by *C difficile* and inappropriate use of broad-spectrum antibiotics or prolonged courses of prophylactic antibiotics puts all patients at risk of developing antibiotic-resistant pathogens.

Avoid hair removal unless necessary for the procedure. Razors should never be used and generally shaving should be avoided before surgery. When necessary, hair should be removed with clippers right before surgery—but not in the operating room itself.

Tight glucose control is important in patients who undergo cardiac surgery. Note that “glucose control” here is defined as serum glucose levels below 200 mg/dL, collected at or closest to 6:00 AM on each of the first 2 postoperative days.

The literature indicates that patients undergoing colorectal surgery have a decreased risk of SSI and other complications if they are not allowed to become hypothermic during the perioperative period.¹⁹

The CDC recommends the following practices as those with the best evidence to minimize the risk of SSIs:

- Whenever possible, identify and treat all infections remote to the surgical site before elective operation and postpone elective operations on patients with remote site infections until the infection has resolved.
- Encourage tobacco cessation. At a minimum, instruct patients to abstain for at least 30 days before elective operation from smoking cigarettes, cigars, pipes, or any other form of tobacco consumption.
- Require patients to shower or bathe with an antiseptic agent on at least the night before the operative day.
- Thoroughly wash and clean at and around the incision site to remove gross contamination before performing antiseptic skin preparation.
- Keep nails short and do not wear artificial nails.
- Perform a preoperative surgical scrub for at least 2 to 5 minutes using an appropriate

antiseptic and scrub the hands and forearms up to the elbows.

- Protect an incision that has been closed primarily with a sterile dressing for 24 to 48 hours postoperatively.
- Provide positive pressure ventilation in the operating room with at least 15 air changes per hour, of which 3 should be of fresh air.
- Keep the operating rooms' doors closed and minimize traffic.
- Sterilize all surgical instruments according to published guidelines. Perform flash sterilization only for patient care items that will be used immediately (eg, to reprocess an inadvertently dropped instrument). Do not use flash sterilization for reasons of convenience, as an alternative to purchasing additional instrument sets, or to save time.
- Wear a surgical mask that fully covers the mouth and nose when entering the operating room if an operation is about to begin or already under way, or if sterile instruments are exposed. Wear the mask throughout the operation.
- Wear a cap or hood to fully cover hair on the head and face when entering the operating room.
- Handle tissue gently, maintain effective hemostasis, minimize devitalized tissue and foreign bodies (ie, sutures, charred tissues, necrotic debris), and eradicate dead space at the surgical site.
- Use delayed primary skin closure or leave an incision open to heal by second intention if the surgeon considers the surgical site to be heavily contaminated.
- Obtain cultures and exclude from duty, surgical personnel who have draining skin lesions until infection has been ruled out or personnel have received adequate therapy and infection has resolved.
- If drainage is necessary, use a closed suction drain. Place a drain through a separate incision distant from the operative incision. Remove the drain as soon as possible.

- Report appropriately stratified operation-specific, SSI rates to surgical team members. The optimum frequency and format for such rate computations will be determined by stratified caseload sizes (denominators) and the objectives of local, continuous quality improvement initiatives.

Many of these elements have been incorporated in a systemic fashion using the surgical checklist. There have been studies that use a before-and-after methodology demonstrating the effectiveness of a surgical checklist. In 2009, Haynes and Gawande reported the effective use of a 19-item checklist in 8 countries in reducing mortality by 46%, complications by 36%, and SSIs by 45%.²⁰ To date there have been few randomized trials that have shown benefits of surgical checklists. The most recent clustered randomized trial was a study of 2 Norwegian hospitals and more than 4000 operations, where complications dropped 42% and length of stay was reduced by 0.8 days with the use of a surgical checklist. Mortality did not change significantly.²¹ The value of the checklists and their elements are based on the best evidence we have to date, but their implementation may be the key to minimizing surgical complications including SSIs.

Catheter-Associated Urinary Tract Infections

CAUTIs are extremely common and costly complications in hospitalized patients. CAUTIs are the most common type of HCAI accounting for more than 30% of all hospital infections. An estimated 13,000 deaths are associated with UTIs each year.⁵ According to the CDC, 75% of UTIs are catheter associated, and 15% to 25% of patients receive a urinary catheter during their hospital stay.²² In the ICU, the incidence of CAUTIs can range from 3.1 to 7.4 per 1000 urinary catheter days.²³ Over \$340 million is estimated to be spent in health care costs attributable to CAUTIs in the United States each year.²⁴ As of October 1, 2008, the Centers for Medicare and Medicaid Services (CMS) no longer reimburse hospitals for the additional costs for caring for patients with CAUTI and consider CAUTI a “reasonably preventable” infection. Since the single most significant risk factor for a CAUTI is the prolonged use of the urinary

catheter, the overriding principle for the prevention of CAUTIs is to minimize any unnecessary catheters by employing systems that ensure that patients have an acceptable indication for a urinary catheter and that catheters are removed as soon as possible.

Appropriate indications for the use of indwelling urinary catheters include urinary tract obstruction, neurogenic bladder dysfunction and urinary retention, and urologic studies or surgery on contiguous structures. Additionally, urinary catheter use is considered appropriate in patients with urinary incontinence and stage III or IV sacral pressure ulcers, as well as for end-of-life care.²³ Other indications for the placement of a urinary catheter in critically ill patient on mechanical ventilation include sepsis (for the first 24 hours), acute respiratory distress syndrome on continuous sedation or who require paralytic agents, continuous renal replacement therapy, acute renal failure, use of vasopressors with titration, temperature management systems, intra-aortic balloon pump, and subarachnoid hemorrhage with triple-H therapy (hypertension, hypervolemia, and hemodilution). Other strategies that are thought to be effective in reducing catheter use and thereby preventing infection include the routine use of a bladder scan to help caregivers identify patients who have urinary obstruction, daily review of the necessity of the urinary catheter, proper insertion technique and maintenance, and decision support tools (both electronic or with paper stop order sets) that are either nurse initiated or nurse prompted to ensure early removal of unnecessary urinary catheters.

In 2007, The Michigan Health and Hospital Association Keystone Center implemented a statewide initiative to reduce unnecessary urinary catheters. The initiative was based on nurse-led multidisciplinary rounds with the use of the “bladder bundle” to aid in the prompt removal of catheters. The efforts lead to a 45% reduction in inappropriate catheter use. The key elements of the “bladder bundle” include the following²⁵:

1. Nurse-initiated urinary catheter discontinuation protocol
2. Urinary catheter reminders and removal prompts
3. Alternatives to indwelling urinary catheterization (such a condom catheters)

4. Portable bladder ultrasound monitoring
5. Insertion care and maintenance

Unfortunately, data from the CDC’s National Healthcare Safety Network (NHSN) reveal that CAUTI rates remain high. There are many possible reasons for this; priority is given to other infections such as VAP, CRBSI, and SSI, and the morbidity and mortality of CAUTI is underappreciated. Most hospitals in the United States do not have a program for CAUTI surveillance, education, or adopt any of the previously mentioned prevention strategies.²⁶

In 2013, the federal government released The National and State Healthcare-Associated Infections Progress Report revealing a 3% increase in CAUTIs between 2009 and 2012.²⁷ At the 2013 Action Planning Conference, a document proposing new targets for the prevention of HAIs was identified in the National Action Plan to Prevent Healthcare-Associated Infections (HAI): Road Map to Elimination. One of the proposal’s goals was to reduce CAUTIs in ICU and ward patients. Based on the CDC’s NHSN data, the proposed 2020 target is a 25% reduction from the 2015 baseline.²⁸

HIV Infection in Critically Ill Patients

Mekeleya Yimen, MD

KEY POINTS

- 1 The acquired immunodeficiency syndrome (AIDS) is caused by human immunodeficiency virus (HIV), a sexually transmitted retrovirus, and characterized by depletion of T-helper (CD4) cells and severe immunodeficiency. Clinically, AIDS is defined as depletion of CD4 cells less than 200 cells/mm³ or development of AIDS qualifying opportunistic infection.
- 2 Effective antiretroviral therapy and chemoprophylaxis has increased the latency phase of HIV infection prolonging asymptomatic disease to several decades.
- 3 Pulmonary complications remain the leading cause of morbidity and mortality in HIV-infected patients. Bacterial pneumonia caused by streptococcus pneumoniae, staphylococcus aureus and tuberculosis are common causes of respiratory illness.
- 4 The prevalence of respiratory failure from Pneumocystis jiroveci pneumonia (PCP) has significantly decreased over the past 2 decades with the use of highly active antiretroviral therapy and prophylaxis with trimethoprim-sulfamethoxazole.
- 5 Adjunctive corticosteroid therapy is recommended to prevent lung injury in severe cases of PCP pneumonia, defined as those with PaO₂ of less than 70 mm Hg or alveolar-arterial oxygen gradient more than 35 mm Hg on room air.
- 6 HIV-infected patients have a higher incidence of pancreatitis due to older nucleoside reverse transcriptase agents, pentamidine, sulfa drugs, isoniazid as well as pathogens, such as cytomegalovirus and cryptosporidium.
- 7 Co-infection with hepatitis B and C viruses is common in HIV patients and can lead to chronic infection, high level of viremia, and early progression to end stage liver disease.
- 8 Neurological complications in HIV and AIDS patients can range from neurocognitive disorders (eg, HIV dementia) to life-threatening opportunistic infections associated with changes in mental status or seizures.
- 9 Metabolic and cardiovascular disorders are common in HIV-infected patients and are frequent causes of morbidity and mortality in the post-highly active antiretroviral treatment era.
- 10 It is usually safer to withhold HIV medications in the critically ill patient. However, if continuing or initiation of antiretroviral agents is warranted, consultation with an infectious disease specialist is recommended.

Immune reconstitution inflammatory syndrome is commonly seen 4 to 6 weeks after initiation of highly active antiretroviral treatment in treatment naive patients
- who are severely immune suppressed (CD4 < 50-100 cells/mm³) and have an opportunistic infection at the time of HIV diagnosis.

INTRODUCTION

Human immunodeficiency virus (HIV) is a sexually transmitted retrovirus composed of RNA (ribonucleic acid) genome and enzymes such as protease, reverse transcriptase and integrase; enveloped within an outer shell that has binding sites for two cell receptors, CCR5 and CXCR4. CXCR4 is a coreceptor found on CD4+ T cells and CCR5 is found on CD4+ T helper cells, macrophages, and dendritic cells. In the first 2 to 3 weeks of acute infection, macrophages and CD4+ T cells are depleted rapidly as the virus replicates within these cells. Clinically, this period manifests as a febrile viral syndrome commonly with symptoms of atypical rash and lymphadenopathy. Seroconversion eventually follows 2 to 4 weeks after primary HIV infection as humoral immunity develops. As the immune system recognizes and destroys systemic viral particles and infected cells, the body enters a long phase of clinical latency and asymptomatic disease. Using the enzyme reverse transcriptase the viral RNA genome is used as a template to make DNA replica which is integrated into human DNA genome by the enzyme integrase leading to chronic viral replication. Over time, the

body loses the ability to replenish infected cell pools especially helper T cells resulting in immune deficiency known as acquired immunodeficiency syndrome (AIDS). Table 41–1 lists common infections that are seen in HIV-infected persons.

AIDS is defined clinically as depletion of CD4 cells less than 200 cells/mm³ (normal > 800) or development of AIDS-qualifying opportunistic infection. Without antiretroviral treatment, progression to AIDS occurs within an average of 8 to 10 years. The availability of effective antiretroviral therapy and chemoprophylaxis for opportunistic infections has increased the latency phase of HIV infection prolonging asymptomatic disease to several decades. Nonetheless, it is estimated that 1 in 6 newly HIV-infected persons are unaware of their infection status and will present with AIDS associated complications at the time of initial diagnosis.

Current armamentarium of antiretroviral drugs successfully suppress viral replication hence delaying loss of CD4 cells and progression to AIDS. But some anatomical sites are poorly penetrated by drugs and act as viral reservoirs (such as latent CD4 cells, central nervous system [CNS] tissue, and lymphoid tissues in

TABLE 41–1 Opportunistic infections in HIV/AIDS patients.

the GI and genital tracts). Within these sites, ongoing viral spread and replication can occur via cell-to-cell transmission and syncytium formation, leading to a chronic proinflammatory state, which in turn has been linked to increased risk of malignancy, autoimmune, and early cardiovascular disease in HIV patients.

Antiretroviral therapy has dramatically changed the spectrum of illness seen in HIV-infected patients. Studies have shown that hospital and ICU admission rates remain unchanged in HIV-infected persons, although their admitting diagnoses appears to have shifted from infectious to noninfectious illnesses. Following is a summary of frequently encountered ICU diagnoses in HIV-infected patients in the current highly active antiretroviral treatment (HAART) era.

PULMONARY COMPLICATIONS

Pulmonary complication in the form of infectious and noninfectious disease remains the leading cause of morbidity and mortality in HIV-infected individuals. The spectrum of infectious complications appears to have changed since the introduction of combination antiretroviral drugs in the mid-1990s. In the early AIDS epidemic, respiratory failure due to *Pneumocystis jiroveci* pneumonia (PCP) was the leading cause of death. Although respiratory failure remains the most common indication for ICU admission, the rates of PCP have declined. Bacterial pathogens such as *Streptococcus pneumoniae*, *Staphylococcus aureus* and tuberculosis are common causes of respiratory failure. In fact, TB is responsible for 1 of 10 HIV/AIDS-related deaths worldwide. As HIV infection is becoming a chronic medical condition with a long-life expectancy, its association with noninfectious respiratory complications is also becoming widely recognized. Reactive airway disease, lung cancer (irrespective of smoking history) and pulmonary arterial hypertension (PAH) are increasingly becoming common indications for ICU admission in HIV-infected patients. [Table 41–2](#) lists the pulmonary complications frequently encountered in critically ill HIV-infected patients.

Pneumonia

Alterations in host defense mechanisms, such as B lymphocyte dysfunction, abnormal secretion of

Viral <ul style="list-style-type: none"> • Seasonal influenza • CMV 	Cardiovascular <ul style="list-style-type: none"> • CHF exacerbation • Pulmonary arterial hypertension
Fungal <ul style="list-style-type: none"> • <i>Pneumocystis jiroveci</i> • Endemic fungi—<i>Histoplasma capsulatum</i>, <i>Coccidioidomycosis</i>, <i>Cryptococcus</i> spp 	Others <ul style="list-style-type: none"> • IRIS • Pneumonitis • COPD/reactive airway diseases

NTM, nontuberculous mycobacteria

immunoglobulin and mucociliary dysfunction, and other risk behaviors, such as tobacco use appear to increase the risk of pneumonia in HIV-infected patients irrespective of CD4 counts or antiretroviral use. *Streptococcus pneumoniae* and *Mycobacterium tuberculosis* are the leading cause of pneumonia but other bacterial, viral, and fungal (especially endemic fungi) pathogens are also prevalent.

Acute respiratory failure is commonly seen with viral and bacterial pneumonias, whereas tuberculosis, PCP, and other fungal infections have more of a subacute presentation. Chemoprophylaxis, vaccination history (pneumococcal and influenza), travel, and endemic exposures are clues when developing a differential diagnosis. Cough, fever, and dyspnea are the most common presenting symptoms.

Basic laboratory workup including lactate dehydrogenase (LDH) and sputum Gram stain and cultures (bacterial, mycobacterial, and fungal) should be obtained. Chest radiography (CXR) showing lobar pneumonia is suggestive of common community-acquired bacterial pathogens including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. Bronchoscopy is of limited value in establishing the diagnosis of bacterial pneumonia in HIV-infected patients with the exception of cases where there is high suspicion for

mycobacterial disease or fungal process. Ancillary testing with urine antigen detection for *Pneumococcus* and *Legionella* have high specificity, but low sensitivity. For the endemic fungi, *Histoplasma*, *Coccidioidomycosis*, and *Cryptococcus* urine or serum antigen detection tests are available but have better yield in the setting of disseminated disease.

Community-acquired pneumonia coverage with third- or fourth-generation cephalosporin plus a respiratory fluoroquinolone (eg, levofloxacin or moxifloxacin) or macrolide (eg, azithromycin) should be initiated in patients presenting with suspected bacterial pneumonia. In severe respiratory failure requiring ICU admission, initial empiric coverage for gram-negative organisms (eg, *Pseudomonas* spp.) and resistant pathogens such as methicillin-resistant *Staphylococcus aureus* should be considered until culture data is available to guide therapy.

Pneumocystis Jiroveci Pneumonia

Since the widespread use of HAART and prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX), the prevalence of PCP-associated respiratory failure has decreased. Commonly presenting symptoms are nonproductive cough, fever, and anorexia evolving over 2 to 4 weeks in an AIDS patient ($CD4 < 200$). Hypoxia is the most common symptomatic and laboratory finding. Elevated LDH along with an alveolar-arterial (A-a) gradient more than 35 mm Hg is suggestive of PCP pneumonia. CXR commonly shows interstitial infiltrates with classic “butterfly” pattern or an atypical presentation with nodular, cavitary, or cystic lesions. In 20% of the cases, the CXR may be normal. Spontaneous pneumothorax in a patient with HIV should raise the suspicion for PCP.

Special stains of induced sputum for cysts or trophozoites are sensitive in less than 60% of cases; thus negative results warrant further investigation with bronchoscopy and bronchoalveolar lavage. Standard stains and techniques used for PCP diagnosis include Giemsa or modified Wright–Giemsa (also known as Diff–Quik), Gomori-methanamine silver, and immunofluorescent staining (direct fluorescent antibody). Recently, polymerase chain reaction (PCR) detection and measurement of 1-3 β -d-glucan levels are gaining wide acceptance in the diagnosis

of PCP associated with AIDS although the utility in non-HIV patients is not yet well defined.

TMP-SMX remains the first-line therapeutic agent for PCP pneumonia. Adjunctive corticosteroid therapy is recommended to prevent lung injury in severe cases, clinically defined as PaO_2 of less than 70 mm Hg or A-a oxygen gradient of more than 35 mm Hg on room air. For those patients who are intolerant to sulfa drugs, IV pentamidine is an alternate choice, but serious side effects including pancreatitis, renal failure, and hypoglycemia limit its use. Other alternative agents include the combination of clindamycin and primaquine, dapsone, and TMX or atovaquone. These regimens may not be ideal in critically ill patients, as primaquine, dapsone, and atovaquone are only available orally. Duration of therapy for PCP pneumonia is 21 days and clinical response is expected within 3 to 5 days. Treatment failure should be suspected if response lags more than 8 days. TMP-SMX is commonly associated with atypical adverse reactions such as fever, hepatitis, and leukopenia, which can be mistaken for treatment failure. The most common side effect reported with TMX-SMX is a rash.

Viral Pneumonitis

HIV-infected individuals are at increased risk of developing serious complications from respiratory viruses especially with the influenza virus. During influenza season, HIV-infected patients are hospitalized at increased rates with influenza-related complications so aggressive preventive care with vaccination should be sought. Unlike the influenza virus, the significance of other viral pathogens such as herpes simplex virus (HSV), cytomegalovirus (CMV), and adenovirus when isolated from respiratory secretions is difficult to interpret and may represent viral shedding. For most patients, this may represent severe immunosuppression and is a sign of poor prognosis. The role of antiviral therapy has been debated and does not seem to show survival improvement.

HIV-Related Pulmonary Arterial Hypertension

The increased prevalence of PAH in HIV-infected patients has been recognized since the 1980s and

seems to occur independent of the severity of immune deficiency or antiretroviral use. These patients usually present with clinical symptoms of chronic dyspnea and lower extremity edema. Doppler echocardiography shows elevated right ventricular and pulmonary pressures but confirmation of the diagnosis of PAH requires right heart catheterization showing mean pulmonary artery pressure more than 25 mm Hg at rest and normal pulmonary capillary wedge pressure less than 15 mm Hg. Conventional treatment with calcium channel blockers is not effective in HIV-PAH and antiretroviral therapy also does not seem to alter the disease course. Standard treatment agents available for PAH seem to have similar efficacy in HIV-infected patients but drug–drug interactions with antiretroviral agents (especially protease inhibitors, PIs) must be considered.

GASTROINTESTINAL COMPLICATIONS

Most gastrointestinal (GI) manifestations associated with HIV infection do not warrant ICU level of care. Infections that have predilection for the GI tract, such as *Candida*, CMV, HSV, and *Mycobacterium avium intracellulare* (MAI) cause mucosal disease and commonly manifest with symptoms of odynophagia, dysphagia, and anorexia. Catastrophic complications rarely can develop, such as bowel perforation, obstruction, and life-threatening hemorrhage. In addition, compromise of the mucosal integrity of the GI tract allows gut translocation of bacteria leading to sepsis and septic shock. Pancreatitis and complications of liver disease are also frequent and common indications for ICU admission.

Pancreatitis

A higher incidence of pancreatitis has been reported in HIV patients related to multiple factors. Medications especially older nucleoside reverse transcriptase agents, such as didanosine/stavudine are common culprits. As a class, PIs are known to cause dyslipidemia including hypertriglyceridemia, which may increase the risk of hyperlipidemic injury to the pancreas. Drugs used to treat opportunistic infections, such as pentamidine, sulfa drugs, and isoniazid also cause pancreatitis. Certain pathogens

associated with HIV/AIDS, such as CMV and *Cryptosporidium* have a predilection for the pancreas.

A common presenting complaint is abdominal pain with laboratory data showing elevated amylase or lipase levels. Imaging with CT shows inflammation of the pancreas. Further workup with fine needle aspiration may be helpful in ruling out infectious causes of pancreatitis but is seldom performed. Treatment in most cases is supportive.

Liver Disease

Due to shared risk factors, coinfection with hepatitis B and C is common in HIV patients. HIV virus is known to accelerate liver disease in coinfecting patients leading to chronic infection, high levels of viremia and early progression to end-stage liver disease. Hepatic steatosis in association with and without alcohol and medications is also common in HIV patients. Liver disease accounts for 20% of non-AIDS-related mortality in HIV patients. Complications associated with end-stage liver disease, such as hepatic encephalopathy, variceal bleeding, and other organ failures are common indications for ICU admission. Management does not differ from the general population and focuses on preventing further liver damage, slowing the progression of liver disease, and management of cirrhotic complications.

Hepatitis B and HIV Coinfection

Initiation and discontinuation of antiviral therapy in HIV-HBV coinfecting patients should be cautiously performed. The choice of antiretroviral agent must also consider treatment of both infections and must avoid monotherapy of hepatitis B virus due to the increased rates of acquiring drug resistance. [Table 41–3](#) lists the medications that are effective

TABLE 41–3 Medications effective against HIV and HBV.

HIV/HBV	HBV Treatment, But Some Activity Against HIV
Lamivudine Emtricitabine Tenofovir	Adefovir Entecavir

against both HIV and HBV. Ideally, two of the combination antiretroviral HIV medications should be active against HBV. Treatment discontinuation should be avoided if possible, as severe a flare of HBV has been reported with withdrawal. Immune reconstitution syndrome, which commonly presents within 2 months of antiretroviral initiation can also present with hepatitis flare.

Hepatitis C and HIV Coinfection

Hepatitis C infection does not appear to affect the course of HIV disease, but as in the case of HBV infection, liver disease is accelerated with HIV-HCV coinfection. Drug-induced liver injury is also common in coinfecting patients. The mainstay of HCV therapy is PEG interferon and ribavirin, but a newer class of agents has recently been introduced for specific genotypes of HCV. These agents are PIs that are metabolized by the liver cytochrome P450 system and may interact with many drugs including antiretroviral agents. Complications from cirrhosis and end-stage liver disease are also of concern in the ICU setting. Many studies have shown acceleration to liver failure, noncirrhotic portal hypertension, and hepatocellular carcinoma with HIV-HCV coinfection. Early consideration for liver transplantation is warranted in these settings. Management of these complications is identical as in non-HIV-infected patients.

CENTRAL NERVOUS SYSTEM COMPLICATIONS

Neuro-AIDS is a terminology used to describe the neurological complications in HIV and AIDS patients. These complications range from neurocognitive disorders, such as HIV dementia to opportunistic infections that cause life-threatening acute illnesses that most commonly present with change in mental status, seizures, or weakness. Evaluation of these symptoms frequently mandates hospitalization and with severe symptoms, ICU admission is indicated.

Neurological manifestations of HIV have changed since the widespread availability of HAART. Neurocognitive disorders and neuropathies are becoming more prevalent as opportunistic infections and malignancies of the CNS remain fatal, but

less frequently encountered in the Western world. Cerebral toxoplasmosis, primary CNS lymphoma (PCNSL), and Cryptococcal meningitis are frequently encountered in HIV/AIDS patients in the ICU setting as severe symptoms, such as acute encephalopathy, seizures, cerebral edema, or increased intracranial pressure are associated with these diagnosis. Nonetheless, HIV-infected patients are also at risk for community-acquired meningitis/encephalitis and vascular disorders, such as strokes. The primary goal in management is securing the airway and symptomatic treatment, such as seizure control while undergoing the appropriate workup.

Cerebral Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoa acquired via consumption of undercooked meats (commonly beef or pork) or via exposure to cat feces (usual carriers of oocytes). Primary infection usually presents with a mononucleosis-like illness and is usually subclinical and self-limiting. Prior exposure to toxoplasmosis is diagnosed by antibody detection (IgG for *T. gondii*). Seroprevalence is variable throughout the world. In the United States, 15% of the population has prior exposure. In France and developing countries, higher seroprevalence rates (> 50%) have been reported. Latent cysts can reactivate in the setting of severe immune suppression and cause devastating illness, such as encephalitis, chorioretinitis, myocarditis, and pneumonitis.

Toxoplasma encephalitis (TE) is the most common manifestation in AIDS patients (CD4 counts < 50). It usually presents with fever, headache, and change in mental status. Imaging with contrast MRI or CT shows single or multiple ring-enhancing lesions. Unfortunately, these radiographic findings are nonspecific and may be seen with other CNS infections and malignancies, such as PCNSL. TE is usually a clinical diagnosis in AIDS patients. The presence of multiple lesions or a single ring-enhancing lesion (especially basal ganglia lesions) in a *Toxoplasma* IgG seropositive patient warrants presumptive treatment. The preferred treatment regimen is sulfadiazine/pyrimethamine with leucovorin (to prevent bone marrow suppression commonly seen with prolonged pyrimethamine use). Treatment duration is 6 weeks with follow-up imaging after 2 weeks to document radiographic improvement. If clinical improvement is

not seen at this point, further diagnostic workup, usually a brain biopsy is warranted to rule out PCNSL. In the pre-HAART era, life-long suppressive therapy was mandatory following diagnosis of TE, but with effective antiretroviral therapy, it is now generally continued until immune reconstitution (CD4 rise > 200). It is also worth noting that rates of TE have decreased with widespread use of chemoprophylaxis with sulfa-based drugs for PCP, which is also effecting in preventing toxoplasmosis.

Primary CNS Lymphoma

Primary CNS lymphoma (PCNSL) is an AIDS-defining illness with a prevalence of approximately 5% pre-HAART, but a significant reduction has been seen in recent years. PCNSL is a non-Hodgkin's B-cell lymphoma that is thought to result from malignant transformation of chronically activated EBV infected B cells. Clinical presentation and radiographic findings are similar between TE and PCNSL. Patients present with headache, change in mental status, and visual disturbances, and CT/MRI usually shows a contrast-enhancing lesion. CSF fluid with EBV PCR presence or cytology showing malignant cells is also supportive of diagnosis, but has low yield. Some studies have supported the use of functional imaging studies such as single photon emission computed tomography or positron emission tomography scan to differentiate between TE and PCNSL (especially when a single CNS mass lesion is present). Increased tracer uptake with these studies is suggestive of PCNSL, but should not be used as a definitive diagnosis. In clinical practice, AIDS patients presenting with a contrast enhancing lesion are treated with a trial of toxoplasma therapy with close clinical and imaging follow up, and brain biopsy is pursued if clinical improvement is not attained after 2 weeks.

Treatment for PCNSL is whole brain radiation and chemotherapy, which includes high dose corticosteroids, which are effective as antitumor agents but also treat tumor-associated edema.

Cryptococcal Meningitis

Cryptococcus neoformans is a saprophytic fungus abundant in the environment. Disease results from inhalation of spores, which usually causes self-limited acute respiratory infection. In immunocompromised hosts, disseminated disease to multiple sites including

skin, prostate, bone marrow, and CNS can develop. In HIV/AIDS patients, cryptococcal meningitis is the most common presentation and is thought to arise from hematogenous spread following cryptococemia in acute infection or from reactivation of latent disease (especially in those with CD4 counts < 100). Patients commonly present with indolent symptoms, such as headache, malaise, and fevers, but in delayed diagnosis obtundation and seizures may warrant ICU level of care. Imaging with CT or MRI of the brain should be performed first to rule out intracranial lesions, but rarely hydrocephalus or infectious granulomas (cryptococcoma), which present as non-contrast enhancing well-circumscribed lesions may be present. CSF analysis should be performed when *Cryptococcus* is suspected along with measurement of opening pressure. Lumbar puncture may show CSF pleocytosis with low glucose and elevated opening pressure (> 20 cm H₂O). Cryptococcal antigen from both serum and CSF are highly sensitive and specific tests. Cryptococcal CSF antigen is nearly 100% sensitive as compared to India ink stains (75% sensitivity) in the case of meningitis, and serum is approximately 95% sensitive and useful when lumbar puncture cannot be performed. Treatment of cryptococcal meningitis includes antifungal therapy and management of intracranial pressure. Treatment duration is for 10 weeks starting with liposomal preparation of amphotericin plus flucytosine induction for the first 2 weeks followed by consolidation therapy with fluconazole for the next 8 weeks. Maintenance with lower dose fluconazole should be continued until sustained immune reconstitution is attained (CD4 > 200). In those patients with opening pressure more than 25 cm H₂O, daily lumbar puncture needs to be performed to reduce pressure (< 20 cm H₂O or by 50%); lumbar drain or ventriculoperitoneal shunt may be warranted for persistently elevated ICP.

HEMATOLOGIC COMPLICATIONS

Cytopenias are the most common complication of HIV disease and develop as a result dysregulated of cytokine release encountered in HIV infection, bone marrow suppression due to medication and infiltration of bone marrow by opportunistic infections that is, CMV, *Cryptococcus*, *Histoplasma*, *Mycobacteria*

(MTB, MAI), or malignancy (ie, lymphoma and Kaposi sarcoma).

Anemia

Anemia of chronic disease is the most common cytopenia encountered, and is frequently associated with use of drugs such as Zidovudine (AZT). Discontinuation of medication and supportive care is the standard of care. Rarely severe anemia may mandate ICU admission as in the case of parvovirus B19 infection or drug-induced hemolytic anemia (eg, use of dapsone in G6PD-deficient patients, primaquine, and ribavirin). Although parvovirus B19 infection causes a self-limited disease in immunocompetent hosts, AIDS patients (especially with CD4 count < 100) are unable to eradicate the infection and may develop pure red cell aplasia. Management includes transfusions, supportive care, and a 5-day course of IV immune globulin.

Hemolytic anemia is rare in HIV disease, but can be seen in association with medication use as in the case of G6PD deficiency and in the setting of thrombotic thrombocytopenic purpura (TTP). Because G6PD deficiency is the most common enzymatic disorder worldwide (especially in African and Mediterranean descendants), preemptive evaluation of patients for G6PD deficiency prior to initiation of drugs known to cause hemolysis is the best management approach. Once complications develop, treatment is usually supportive.

Neutropenia

Prolonged neutropenia is common especially in end-stage HIV disease. HIV associated neutropenia is highly responsive to colony stimulating factors. Neutropenic sepsis is a rare complication, as HIV patients develop gradual neutrophil depletion and mucosal integrity is usually preserved unlike the neutropenia that occurs in cancer patients.

Thrombocytopenia

Thrombocytopenia can develop as a result of idiopathic (immune) thrombocytopenic purpura (ITP) and TTP. The pathogenesis of ITP is related to autoantibodies generated during HIV infection. For most patients, it may be the initial manifestation of HIV disease. Management is with pulse dose

corticosteroids and if unresponsive to corticosteroid therapy, splenectomy may be warranted.

HIV is also known to be one of the triggers for TTP. TTP is a rare but life-threatening hemolytic process characterized by pentad of fever, neurologic changes (altered mental status and seizures), renal failure, microangiopathic hemolytic anemia, and thrombocytopenia. Standard diagnostic tests to evaluate for hemolysis and renal failure should be obtained. Since disease may progress to fatal outcomes, prompt recognition and initiation of treatment with plasmapheresis and possibly corticosteroids is essential.

METABOLIC AND CARDIOVASCULAR DISORDERS

Insulin resistance, dyslipidemia, and abnormal fat distribution are common metabolic changes encountered in HIV-infected individuals that are not only directly related to the pathogenesis of HIV infection, but also medications used to treat HIV disease. Several studies have shown an increased rate of early cardiovascular disease associated with prolonged exposure to certain classes of antiretroviral agents (PIs and nucleoside reverse transcriptase agents), but also with their discontinuation. The pathogenesis of heart disease in HIV patients is multifactorial and likely related to the proinflammatory state caused by HIV infection along with the metabolic changes and accelerated rate of atherosclerotic disease. Cardiac events are the leading cause of morbidity and mortality in HIV patients in the post-HAART era. Traditional risk factors along with the socioeconomic status of the HIV population also heighten this risk. Therapeutic measures do not differ in HIV patients with the exception of the need for increased awareness of drug–drug interactions when initiating medical management.

HAART IN THE ICU

Initiation of antiretroviral therapy usually is reserved for the outpatient setting, as genotypic and resistance testing must be performed even in treatment-naïve patients. A common concern

encountered in the ICU setting is the question of continuing HIV therapy in the critically ill patient. Critical care providers should be aware of the numerous drug interactions associated with antiretroviral agents. In addition, the erratic drug absorption from the GI tract in the critically ill, need for dose adjustment in the setting of renal and hepatic dysfunction, risk for Immune Reconstitution Inflammatory Syndrome (IRIS) should be considered. It is usually safer to withhold HIV medications in the critically ill patient, but in the rare instances where continuing or initiation of antiretroviral agents is warranted, it should be done in consultation with an infectious disease specialist.

IRIS is a rare atypical inflammatory disorder usually associated with immune recovery. Patients may present with paradoxical worsening or development of an opportunistic infection, or a new autoimmune process. The pathogenesis is thought to be recovery of cellular and humoral immunity with improvement in CD4 cell counts. It is commonly seen 4 to 6 weeks after initiation of HAART in treatment-naïve patients who are severely immunosuppressed ($CD4 < 50-100$) and have an opportunistic infection at the time of HIV diagnosis. Common disease processes presenting in the setting of IRIS are mycobacterial diseases (MTB, MAI), *Cryptococcus*, and CMV. Treatment requires close observation, while continuing HAART and treating the opportunistic infection. The role of corticosteroids and nonsteroidal anti-inflammatory drugs is unclear, but commonly utilized in an attempt to subdue the inflammatory reaction.

Sepsis, Septic Shock, and Multiple Organ Failure

Russell J. McCulloh, MD and Steven M. Opal, MD

KEY POINTS

- 1 Sepsis is increasing in incidence worldwide. This is the result of a number of factors including: the aging of the population with a large increase in patients more than 65 years; progressive increase in antibiotic resistance; increased reliance on implanted devices, organ transplantation and other invasive surgical procedures; and increasing prevalence of patients with long-term immunosuppressive diseases and medications who are at risk for severe infection and sepsis.
- 2 Sepsis is a syndrome consisting of a constellation of signs, symptoms, hemodynamic, and laboratory findings caused by an excessive and/or dysfunctional host immune response to severe infection. There is currently no single diagnostic test sufficient to make a definitive diagnosis of sepsis.
- 3 The key to optimal care of the septic patient is early recognition and early initiation of appropriate treatment. This places the responsibility for early recognition on the health care team in managing acutely ill patients. The lack of a rapid diagnostic test and the often subtle initial presentation of sepsis make the early detection of sepsis a real challenge.
- 4 Septic shock is a medical emergency and should be treated as such. The major therapeutic approach is aggressive fluid resuscitation, early and appropriate antibiotic therapy, early determination of the source of the causative infection site and source control if possible (drain abscess, remove necrotic tissue or infected catheters or other devices, etc).
- 5 The prevention and expert management of organ dysfunction as a result of sepsis is critical for survival and prevention of long-term disability. Expert supportive care by critical care specialists will improve outcomes.

INTRODUCTION

Sepsis and the multiorgan failure that often accompanies the systemic inflammatory response syndrome (SIRS) is a leading cause of mortality in the intensive care unit. Over 750,000 patients develop sepsis annually in the United States accounting for about 10% of all intensive care unit (ICU)

admissions. Of these patients, 5% to 15% will be diagnosed with septic shock. The hospital mortality for septic shock remains approximately 35% to 54%, despite concerted efforts to improve the treatment options and outcome.

Although modest improvements in the prognosis have been made over the past 2 decades and

promising new therapies continue to be investigated, innovations in the management of septic shock are still required. This chapter will describe the molecular pathophysiology of sepsis, current diagnostic and therapeutic strategies, and the management of septic shock.

SEPSIS DEFINITIONS

New definitions for sepsis were published by the Third International Sepsis Task Force in 2016. According to these updated definitions, sepsis is defined as a life-threatening condition caused by a dysregulated host response to infection accompanied by acute organ dysfunction. Septic shock is a subset of sepsis in which underlying cellular metabolism abnormalities are sufficiently profound to significantly increase mortality. Septic shock is clinically recognized as arterial hypotension, refractory to simple fluid resuscitation, with evidence of hyperlactatemia. Multiple

other clinical entities related to sepsis, including SIRS and multiple organ dysfunction syndrome (MODS) are defined in Table 42–1. These definitions account for the finding that sepsis can result from various infectious agents and microbial mediators and is not necessarily associated with bloodstream infection. The goal of the updated definitions is to increase consistency for epidemiologic studies and clinical trials and to help improve earlier recognition and timely management of patients with sepsis or at risk for developing sepsis.

Current sepsis definitions are based upon the fact that the dysregulated immune response itself, not the infectious agent, underlies the pathophysiology of the septic process. The nature of the causative microorganism also clearly contributes to the ultimate fate of the patient. Pathogens differ in their susceptibility to host defenses, their potential for developing antimicrobial resistance, and their ability to generate toxins—all of which affect pathogenicity.

TABLE 42–1 Common definitions and terms used in sepsis.

Term	Definition	Comments
ARDS* (acute respiratory distress syndrome)	Acute onset (< 7 days) respiratory symptoms; bilateral infiltrates on chest radiograph not explained by other pleural or lung disease; infiltrates not due to cardiac failure or fluid overload (must exclude hydrostatic edema if suspected)	A severity score divides patients into 3 groups depending on PaO ₂ /FiO ₂ ratio and predict outcome: 200 to ≤ 300 mm Hg (mild 27 ± 3% mortality); 100 to ≤ 200 mm Hg (moderate 32 ± 3% mortality) or ≤ 100 mm Hg (severe 45 ± 2% mortality)
Bacteremia	Detection of viable bacteria in the bloodstream	Transient bacteremia without clinical symptoms can occur; bacteremia may or may not be present in sepsis
SIRS (systemic inflammatory response syndrome)	Temperature > 38.5°C (101.3°F) or < 36° C (96.8°F) Tachypnea (> 20 breath/min) Tachycardia (> 90 beat/min) WBC count > 12,000 cells/mm ³ or > 10% immature forms or < 4000 cells/mm ³	Two or more criteria needed; may be caused by infectious and noninfectious etiologies; clinical features attributable to systemic release of inflammatory mediators into the circulation
Sepsis	Life-threatening acute organ dysfunction caused by a dysregulated host response to infection. Organ dysfunction: acute change in SOFA score ≥ 2 points from infection	May be caused by viral, bacterial, fungal, or parasitic pathogens; bloodstream infection need not be present
Septic shock	Sepsis with hypotension requiring vasopressors to maintain MAP ≥ 65 mm Hg and having a serum lactate level > 2 mmol/dL despite adequate volume resuscitation	Hospital mortality in septic shock exceeds 40%

The 2012 Berlin definition (JAMA 307; 2526, 2012) now supersedes the former 1994 European-American Consensus Committee on ARDS definition. P_aO₂, arterial oxygen tension; F_iO₂, fraction of inspired oxygen; WBC, white blood count.

Failing to account for these differences in microbial virulence limits the utility of current sepsis definitions.

Many patients who present with sepsis have multiple predisposing factors, a variety of preexisting illnesses, and have major underlying organ dysfunction from comorbid diseases. The degree to which sepsis contributes to further disordered organ function is difficult to accurately determine. Similarly, the degree to which sepsis contributes to the mortality in patients with other serious underlying diseases (attributable risk of mortality) can be difficult to quantify. Further refinements in sepsis terminology may be possible when rapid diagnostic techniques become available to assess the immune status of septic patients. Functional genomics and proteomics may assist in characterizing septic patients in the future.

EPIDEMIOLOGY

Between 1979 and 2000, the incidence of sepsis in the United States increased by 8.7% annually, from 82.7 to 240.4 per 100,000 population. These trends are observed worldwide and will likely continue because sepsis incidence increases with the aging of the population. Innovations in organ transplantation, implanted prosthetic devices, and long-term vascular access devices continue to expand this vulnerable patient population at risk for sepsis. The gradual aging of the population in many developed and developing countries and the increasing prevalence of antibiotic-resistant microbial pathogens also contribute to the rising incidence of septic shock.

PATHOGENESIS: MICROBIAL FACTORS

Causative Microorganisms

The microbiology of sepsis continues to evolve due to changes in microbial epidemiology, pathogen virulence, and pathogens' susceptibility to antimicrobials. The predominant microbial pathogens responsible for sepsis in the 1960s and 1970s were enteric gram-negative bacilli and *Pseudomonas aeruginosa*, but switched to predominantly gram-positive bacterial pathogens in the mid-1980s through

2010, due mostly to the rapid development of antibiotic resistance in gram-positive pathogens and their strong association with vascular-catheter-associated infections. Gram-negative bacterial pathogens are now returning as the dominant cause of sepsis, due largely to progressive antibiotic resistance and the lack of new antibacterial agents effective against gram-negative bacterial pathogens. Opportunistic fungal pathogens are also increasing in frequency as a cause of sepsis.

Bacterial Endotoxin and Other Pathogen-Associated Molecular Pattern Molecules

Bacterial endotoxin, or lipopolysaccharide (LPS), is an intrinsic component of the outer membrane of gram-negative bacteria and is essential for the viability of enteric bacteria. Endotoxin functions as an alarm molecule alerting the host to invasion by gram-negative bacteria. Endotoxin in the circulation provokes a vigorous systemic inflammatory response. Humans are especially susceptible to the profound immunostimulant properties of endotoxin; even minute doses may be lethal. Other highly conserved pathogen-associated molecular pattern molecules such as bacterial lipoteichoic acid, lipopeptides and even sequences of bacterial and viral DNA can be detected by the immune system and activate innate immune responses.

The Toll-like receptor (TLR) family is the most important cellular, pathogen-associated pattern recognition receptor system in humans. The TLRs are transmembrane receptors for detecting endotoxin and many other microbial mediators, such as peptidoglycan, lipopeptides, bacterial flagellin, lipoteichoic acid, microbial-derived nucleic acids, and viral and fungal cell components. Nucleoside oligomerization domain proteins recognize specific components of bacterial peptidoglycan and other microbial elements with the cytosol and activate the acute phase response with the release of the proinflammatory cytokine interleukin-1 beta.

Other pattern-recognition molecules include alternative complement components, mannose-binding lectin, and CD14. The innate immune system is a nonspecific, rapid response system, making this system a critical survival mechanism in the

initial stages of infection. However, widespread activation of the innate immune system and its cellular components (neutrophils, monocytes, macrophages, and natural killer [NK] cells) can cause collateral damage to host tissues and contributes to the induction of multiorgan injury and septic shock.

In human blood and body fluids, LPS signaling is mediated by interactions with the acute-phase plasma protein LPS-binding protein (LBP). LBP binds to polymeric LPS aggregates and transfers LPS monomers to CD14. After docking to membrane-bound CD14, LPS is delivered to the extracellular adaptor protein MD2. The LPS-MD2 complex is then presented to the extracellular domain of TLR4. This subsequently triggers a signal to the intracellular space that activates LPS-responsive genes. CD14 also binds to bacterial peptidoglycan and lipopeptides and delivers these ligands to TLR2.

TLR4 binding to LPS leads to sequential activation of specific tyrosine and threonine/serine kinases and phosphorylation, ubiquitylation, and degradation of inhibitory κ B (I- κ B) along with other transcriptional activators. I κ B degradation releases nuclear factor κ B (NF- κ B) from the cytoplasm. NF- κ B then translocates into the nucleus and increases transcription of genes encoding clotting elements, complement, other acute phase proteins, cytokines, chemokines, and nitric oxide synthase. The outpouring of inflammatory cytokines and other inflammatory mediators after LPS exposure contributes to SIRS and is central to the pathogenesis of septic shock induced by gram-negative bacteria.

Bacterial Superantigens

Bacterial superantigens comprise a diverse group of protein-based exotoxins from streptococci, staphylococci, and other pathogens that all share the capacity to bind to specific sites on major histocompatibility class II molecules on antigen presenting cells and activate large numbers of CD4⁺ T cells, bypassing the usual mechanism of antigen processing and presentation. Superantigens bind to and cross-link to a limited number of V β regions of the T cell receptor on CD4⁺ T cells, along with the costimulatory molecule CD28. This bridging complex brings CD4⁺ T cells and macrophages into close proximity, which activates both the monocyte-macrophage and T cell populations.

Superantigens can stimulate up to 10% to 20% of the entire circulating lymphocyte population, compared to only about one in 10⁵ circulating lymphocytes stimulated by typical bacterial antigens. This stimulation results in excessive activation of lymphocytes and macrophages, which leads to uncontrolled inflammatory cytokine synthesis and release. Superantigen-induced immune activation may terminate in septic shock (eg, streptococcal toxic shock syndrome) if the process is left unchecked. Infections associated with release of both bacterial superantigens and endotoxin may be particularly injurious to the host; the toxicity of bacterial endotoxin is greatly enhanced by superantigens that prime the immune system to react to endotoxin in an overly sensitized manner.

Other Microbial Mediators

During periods of prolonged systemic hypotension such as septic shock, redistribution of blood flow to the tissues results in splanchnic vasoconstriction. This ischemia and subsequent reperfusion of the gastrointestinal tract disrupts the intestinal mucosal barrier to bacterial products and damaged tissue releases host-derived alarmins that further activate inflammatory signaling. Translocation of microbial components such as bacterial endotoxin occurs from the GI tract to the circulation during periods of severe stress and hypoperfusion of the GI mucosa. Bacterial endotoxin and perhaps other gut-derived microbial mediators might play a pathogenic role in the ongoing inflammatory process after systemic hypotension produced by infectious or noninfectious insults. This finding has initiated interest in attempts to strengthen the GI mucosal barrier function through immunonutrition, epithelial growth factors, and selective decontamination of the GI tract in critical illness, which remain active areas of research.

PATHOGENESIS: HOST-DERIVED MEDIATORS

Cytokine Networks

Inflammatory cytokines play a pivotal role in sepsis pathogenesis. The major proinflammatory cytokines, TNF- α and IL-1 β , induce their hemodynamic and metabolic effects in concert with an expanding group of host-derived inflammatory mediators that

work in a coordinated fashion to produce the systemic inflammatory response (see Table 42–2). The cytokine system functions as a network of communication signals between neutrophils, monocytes, macrophages, and endothelial cells. Autocrine and paracrine activation results in synergistic potentiation of the inflammatory response once it is activated by a systemic microbial challenge. Much of the inflammatory response is localized and compartmentalized in the primary region of initial inflammation. If left unchecked, the inflammatory response enters the systemic circulation, resulting in a generalized reaction culminating in diffuse endothelial injury, coagulation activation, and septic shock. The endocrine-like effect of systemic cytokine and chemokine release drives the inflammatory process and causes coagulation activation throughout the body.

TABLE 42–2 Host-derived inflammatory mediators in septic shock.

Proinflammatory Mediators	Anti-Inflammatory Mediators
Tumor necrosis factor- α	Interleukin-1 receptor antagonist
Interferon gamma	Soluble tumor necrosis factor receptor
Lymphotoxin- α	Soluble interleukin-1 receptor
Interleukin-2	Type II interleukin-1 receptor
Interleukin-8	Transforming growth factor- β
Interleukin-12	Interleukin-4
Interleukin-17	Interleukin-6
Interleukin-18	Interleukin-10
sCD14, MD2	Interleukin-11
Complement components (C5a and C3a)	Interleukin-13
Mannose binding lectin	Prostaglandin E2 α
Leukotriene B ₄	Granulocyte colony-stimulating factor
Platelet-activating factor	Antioxidants
Bradykinin	Anticoagulants
Nitric oxide	(antithrombin, activated protein C, tissue factor pathway inhibitor)
Reactive oxygen species	Interferon alfa
Granulocyte macrophage colony-stimulating factor	Interferon beta
Chemokines	Glucocorticoids
Macrophage inhibitory factor	Epinephrine
High mobility group box I	Cholinergic agonists
Histamine, thrombin, other clotting factors	Resolvins, protectins
TREM-1 (triggering receptor expressed on myeloid cells)	Lipoxygenase pathway

The inflammatory cytokines and chemokines found in excess quantities in the bloodstream in patients with septic shock are matched by a group of anti-inflammatory mediators (see Table 42–2). The proinflammatory mediators tend to predominate locally and in the first 12 to 24 hours of sepsis, whereas the endogenous anti-inflammatory components often prevail systemically in the later phases. Monocyte-macrophage-generated cytokines and chemokines primarily promote sepsis early on; the lymphocyte-derived cytokines and interferons become important in the regulation of later phases of sepsis and may ultimately determine the outcome in septic shock.

CD4+ T Helper Cells

Activated, yet uncommitted, T cells (TH0 cells) have four major pathways of functional differentiation (TH1, TH2, TH17, or Treg cells). TH0 cells exposed to IL-12 in the presence of IL-2 are driven toward a TH1-type functional development. These cells produce IFN- γ , TNF- α , and IL-2 and promote an inflammatory, cell-mediated immune response. TH0 cells exposed to IL-4 will preferentially develop into a TH2-type phenotype; TH2 cells secrete IL-4, IL-10, and IL-13, which promote humoral immune responses and attenuate T helper cells, and myeloid cell activity. Sepsis is often accompanied by a TH2-type response after an initial septic insult, likely due in part to the expression of adrenocorticotrophic hormone, corticosteroids, and catecholamines that promote a TH2 response. CD4 cells are selectively depleted by apoptosis in sepsis further limiting cell-mediated immunity and T helper cell capacity.

A phase of relative immune refractoriness occurs in septic patients that place them at increased risk for secondary bacterial or fungal infection. Part of the pathophysiology of sepsis-induced immunosuppression is mediated by T 17 cells and regulatory T cells. T 17 cells are stimulated by dendritic cell-derived interleukin-23 to produce IL-17, chemokines, and antibacterial and antifungal peptides. T 17 cells are depleted in sepsis and might explain the propensity of septic patients to develop late, opportunistic bacterial and fungal infections. Regulatory T cells expand during sepsis and produce anti-inflammatory cytokines such as IL-10 and transforming growth factor beta contributing to

T cell exhaustion. This pathophysiologic state is associated with endotoxin tolerance, anti-inflammatory cytokine synthesis, and deactivation of monocytes, macrophages, and neutrophils.

The Coagulation System

Activation of the coagulation cascade and generation of a consumptive coagulopathy and diffuse microthrombi are well-recognized events in sepsis. The tissue factor pathway (also known as the extrinsic pathway) is the predominant mechanism by which the coagulation system is activated. The contact factors in the intrinsic pathway are also activated, which helps perpetuate clotting and secondarily initiates vasodilation through bradykinin generation. Activation of intravascular coagulation results in microthrombi and contributes to microcirculatory dysfunction and the multiorgan failure that occur in septic patients. Depletion of coagulation factors and activation of plasmin, antithrombin III, and protein C may subsequently lead to a hemorrhagic diathesis. Depletion of these endogenous anticoagulants may secondarily lead to a procoagulant state and portend a poor prognosis.

Neutrophil–Endothelial Cell Interactions

The recruitment of neutrophils to an area of localized infection is an essential component of the host inflammatory response. Localization and eradication of invading microbial pathogens at the site of initial infection is the principal objective of the immune response to microbial pathogens. This physiologic process becomes deleterious if diffuse neutrophil–endothelial cell interactions occur throughout the circulation in response to systemic inflammation.

Complex mechanisms govern the migration of neutrophils from the intravascular space into the interstitium, where invasive microorganisms may reside. Activated neutrophils degranulate, exposing endothelial surfaces and surrounding structures to reactive oxygen intermediates, nitric oxide, and a variety of proteases. This process contributes not only to microbial clearance but also to diffuse endothelial injury in the setting of systemic inflammation.

Nitric Oxide

Nitric oxide is a highly reactive free radical that plays an essential role in the pathophysiology of septic shock. Its half-life of 1 to 3 seconds limits its activity to local tissues, where it is first generated by nitric oxide synthase. Full expression of inducible nitric oxide synthase requires TNF- α , IL-1, LPS, and probably other regulatory elements.

Nitric oxide is the major endothelial-derived relaxing factor that initiates the vasodilation and systemic hypotension observed in septic shock. Nitric oxide activates guanylate cyclase, which increases cyclic guanosine monophosphate levels inside vascular smooth muscle cells. This results in systemic vasodilation and decreased vascular resistance. Excessive and prolonged release of nitric oxide results in generalized vasodilatation and systemic hypotension.

Nitric oxide also helps increase intracellular killing of microbial pathogens and regulation of platelet and neutrophil adherence in septic patients. It is a highly diffusible gas that does not require specific receptors to cross cell membranes. In the presence of superoxide anion, nitric oxide leads to the formation of peroxynitrite and highly cytotoxic molecules, such as hydroxyl radicals and nitrosyl chloride, which then initiate lipid peroxidation and cause irreversible cellular damage. Nitric oxide inhibits a variety of key enzymes in the tricarboxylic acid pathway, the glycolytic pathway, DNA repair systems, electron transport pathways, and energy-exchange pathways. Because of its potent reactivity, nitric oxide alters the function of many metallo-enzymes, carrier proteins, and structural elements.

Late Host-Derived Mediators

Macrophage migration inhibitory factor is a late mediator that activates immune cells, upregulates TLR4 expression, and contributes to lethal septic shock. This corticosteroid-regulated mediator promotes inflammation and has become a target for therapeutic agents in sepsis. The nuclear protein high-mobility group box-1 protein is released into the extracellular space with cell injury and necrosis and also participates in late-onset inflammatory phase of septic shock.

Pathogenesis: Organ Dysfunction

The diffuse endothelial injury accompanying septic shock results in organ dysfunction distant from the original site of the septic insult. The signal that results in diffuse endovascular injury is thought to be relayed by plasma factors (eg, inflammatory cytokines, complement, kinins, and other host-derived inflammatory mediators) or cellular signals from immune effector cells.

Inadequate tissue blood supply and repeated episodes of ischemia-reperfusion produces MODS. The failure of the microcirculation to support tissue maintenance may result from capillary bed hypoperfusion, blood flow redistribution within vascular beds, functional arteriovenous shunting, blood flow obstruction from microthrombi, platelet or white blood cell aggregates, or abnormal red blood cell deformability. Nitric oxide, reactive oxygen intermediates, inflammatory cytokines, and apoptosis inducers may directly damage endothelial surfaces. Endothelial swelling shifts intravascular fluid into extravascular and intracellular spaces, mechanically obstructing capillary lumens and further limiting microvascular blood flow.

Myocardial performance and pulmonary function also diminish over the course of septic shock and may contribute to the development of MODS. Myocardial contractility decreases in response to various myocardial depressant factors. TNF- α is a prominent cause of myocardial dysfunction; IL-1, IL-6, nitric oxide, and other host-derived inflammatory mediators may be contributing factors. Acute lung injury occurs in septic shock as a result of damage to pulmonary vascular circulation and excess permeability of alveolar capillary membranes. A supply-dependent dysoxia, along with altered capacity for oxidative phosphorylation (cytopathic hypoxia), likely contributes to tissue injury and multiorgan failure in sepsis.

DIAGNOSTIC APPROACH TO SEPSIS

Clinical Features

In his classic treatise on human nature (The Prince, circa 1505), Machiavelli states, “Hectic fever [meaning sepsis] at its inception is difficult to recognize

but easy to treat; left untended, it becomes easy to recognize but difficult to treat.” This statement is as true today as it was 500 years ago. Fully developed septic shock is a readily apparent clinical syndrome that is seldom confused with other pathologic states. However, the early phases of septic shock may be quite subtle even in carefully monitored patients. Although fever is characteristic, hypothermia may occur and connotes a poor prognosis. Unexplained tachycardia and tachypnea are often part of the systemic inflammatory response seen in sepsis. It is important to note that many noninfectious diseases may masquerade as sepsis such as acute pancreatitis, pulmonary emboli, myocardial infarction, blood transfusion reactions, and organ transplant rejection. A summary of the major hemodynamic findings of sepsis is provided in Table 42–3.

Laboratory Indicators of Sepsis and Septic Shock

The updated international guidelines use the Sequential [Sepsis-Related] Organ Failure Assessment Score to define sepsis (SOFA, see Table 42–4). Laboratory criteria included in the SOFA focus on the presence of coagulopathy, hepatic dysfunction, and/or renal dysfunction. Other nonspecific laboratory criteria, such as peripheral white blood cell count can aid in the general diagnosis of infection but are no longer used to define sepsis or septic shock.

White Blood Cell Count and Differential

Either leukocytosis or leukopenia may occur in sepsis. An absolute lymphocyte count less than 1200 cells/mm³ and a ANC:ALC ratio more than 10 have been found to be better predictors of bacteremia than the total white blood cell count or absolute neutrophil count. Interesting, eosinopenia (< 40%) is as useful as C reactive protein in distinguishing SIRS as an immunologically regulated response to infection and SIRS from sepsis.

Coagulation Parameters

Systemic inflammation induced during sepsis can activate the coagulation cascade. In a clinical trial of recombinant human activated Protein C in patients with severe sepsis more than 95% of patients had

TABLE 42–3 Common hemodynamic findings in sepsis.

Parameter	Typical Findings	Comments
Heart rate	≥ 100 beat/min	Major compensatory mechanism for low systemic vascular resistance
Mean arterial blood pressure	< 65 mm Hg	Hallmark of septic shock if it remains low after adequate fluid resuscitation
Cardiac index (cardiac output/m ² [surface area])	> 4 L/min/m ²	Cardiac index usually elevated in early septic shock; may be depressed in late septic shock
Pulmonary arterial occlusion pressure (PAOP)	8-16 mm Hg	Assure that hypovolemia is not the cause of hypotension; perform fluid resuscitation until PAOP returns to normal
Central venous pressure (CVP)	6-12 mm Hg	Reliable resuscitation goal indicating adequate blood volume for ventricular filling pressure
Systemic vascular resistance (SVR)	< 800 dyne/s/cm ⁻⁵	SVR often low in early septic shock; may become elevated in later phases of septic shock
Oxygen delivery (DO ₂) Cardiac index (CI) \times arterial O ₂ content (A)	< 550 mL/min/m ²	Try to provide sufficient DO ₂ to maintain adequate mixed venous O ₂ saturation
Mixed venous O ₂ saturation (SvO ₂) or Central venous O ₂ saturation (ScvO ₂)	$< 70\%$ $< 65\%$	Low mixed venous O ₂ saturation or central venous O ₂ saturation (from superior vena cava) indicates poor oxygen delivery to tissues
Oxygen consumption (VO ₂) (CI) \times (A-VO ₂) $\times 10$	> 180 L/min/m ²	Typically increased in early septic shock

coagulation abnormalities at the time of study entry. Thrombocytosis may occur early as an acute phase response, while thrombocytopenia may occur as a late ominous sign. Additional coagulation findings in severe sepsis are prolongation of the prothrombin time and an increase in fibrin split products or D-dimer. Greater aberrations in coagulation markers are noted in patients with severe sepsis with bloodstream infections compared with those without bloodstream infections. Two endogenous anticoagulants, Protein C and Antithrombin become depleted early on in the development of sepsis far in advance of the development of organ dysfunction.

Chemistries

Unexplained lactic acidemia as a sign of global tissue hypoperfusion occurs in sepsis; a level of more than 2 mmol/dL (18 mg/dL) is a poor prognostic factor and may indicate septic shock as noted earlier. Failure to clear lactate after early fluid resuscitation (> 30 mL/kg intravenous crystalloid) at a rate of at

least 10% per hour is a very poor prognostic sign. Chemistry panels can also be used to detect the presence of sepsis-induced organ dysfunction. Acute kidney injury can be recognized by a rise in the serum creatinine of 0.3 mg/dL or more in 48 hours or a serum creatinine that rise more than 1.5 times baseline levels within the previous 7 days. A total plasma bilirubin more than 4 mg/dL is indicative of sepsis-induced hepatic dysfunction.

Acute Phase Reactants/Biomarkers

Biomarkers that are readily available to most clinicians are the ESR (erythrocyte sedimentation rate) and C-reactive protein (CRP). The use of the ESR has largely been supplanted by the CRP in the evaluation of acute infectious diseases like sepsis. CRP is helpful when normal but is not specific for infection when elevated. CRP can be elevated for days following surgery and will also be elevated in rheumatologic and neoplastic illnesses. Very high CRP levels (> 85 mg/L) is useful in distinguishing

TABLE 42–4 Common laboratory findings in sepsis.

Laboratory Study	Typical Findings	Comments
White blood cell count	Leukocytosis or leukopenia	Stress response, increased margination of neutrophils in sepsis can cause transient neutropenia; toxic granulation
Platelet count	Thrombocytopenia ($< 150,000/\text{mm}^3$)	Look for evidence of fragmentation hemolysis; thrombocytopenia may be accompanied by DIC
Total lymphocyte count	Lymphopenia ($< 1200/\text{mm}^3$)	All lymphocyte types decreased from trafficking out to extravascular sites and excess apoptosis except Treg cells
Eosinophil count	Eosinopenia ($< 40/\text{mm}^3$)	Can suggest infection-related acute inflammatory processes
Coagulation studies	Elevated prothrombin time (INR), aPTT, low fibrinogen levels, elevated D-dimer; evidence of fibrinolysis	Coagulopathy very common, but overt DIC is not common ($< 15\%$ of patients)
Liver enzymes	Elevated alkaline phosphatase, bilirubin, and transaminases; low albumin	These are generally a late finding in sepsis
Blood cultures	Bacteremia or fungemia	Positive blood cultures not required for the diagnosis of sepsis
Plasma lactate	$> 2.2 \text{ mmol/L}$ caused by hypermetabolism, anaerobic metabolism, inhibition of pyruvate dehydrogenase	Poor prognostic feature if not improved rapidly by fluid resuscitation; diagnostic criterion for septic shock
C-reactive protein	Elevated as an acute phase reactant from hepatic synthesis	Acute-phase reactant, sensitive, but not specific for sepsis
Glucose	Hyperglycemia or hypoglycemia	Acute stress response, inhibition of gluconeogenesis can lead to hypoglycemia
Arterial blood gases	Respiratory alkalosis (early); metabolic acidosis (late)	Reduced arterial O_2 content and mixed venous O_2 saturation

DIC, disseminated intravascular coagulation; Treg cells, regulatory T cells; INR, international normalized ratio; aPTT, activated partial thromboplastin time.

infection from non-infectious causes of acute systemic inflammation.

A newer biomarker for the diagnosis of sepsis is serum procalcitonin (PCT). In health, PCT is precursor peptide in calcitonin synthesis by C cells in the thyroid; in septic patients, PCT is generated in prodigious amounts by numerous extra-thyroidal tissues. Elevated levels of PCT are seen 4 to 6 hours after a systemic challenge with endotoxin or other septic stimuli. PCT levels drop quickly following trauma and surgery and are not elevated by malignancies or rheumatologic diseases. PCT is an FDA approved test to aid in the risk assessment of patients with sepsis. A recent meta-analysis of studies examining confirms the value of PCT to distinguish sepsis

for noninfectious causes of systemic inflammation. Levels of PCT more than 2 ng/mL is the best cutoff value in the early diagnosis of bacterial sepsis.

An additional biomarker approved by the FDA for assessing the risk of sepsis in the ICU is the endotoxin activity assay (EAA). Endotoxin is a known mediator in the pathogenesis of sepsis and septic shock. The EAA relies upon priming of the endogenous neutrophil population by circulating endotoxin. This chemiluminescent assay compares the respiratory burst by endotoxin in the test sample to the maximum burst when the sample is spiked with excess LPS. In one study, elevated endotoxin levels were found in 58% of patients admitted to a mixed surgical-medical ICU, irrespective of

the reason for admission. Elevated EAA in patients admitted to the ICU portends a greater chance of septic shock and excess mortality.

Use of the SOFA to Assess Sepsis Severity

Hallmark strong predictor of sepsis mortality is the development of organ dysfunction. The SOFA score assesses the degree of organ dysfunction across several domains and has been integrated into the 2016 guidelines for diagnosing sepsis (Tables 42–1 and 42–5). A SOFA score of 2 or more reflects an overall mortality risk of roughly 10% in the setting of suspected infection. Additionally, use of the bedside qSOFA (Quick SOFA) criteria has been validated as a reliable bedside tool for identifying adult patients with suspected infection who are likely to have poor outcomes. Presence of any 2 of the following criteria represents a positive qSOFA: (1) respiratory rate of 22/min or more; (2) altered mentation (defined as any Glasgow Coma Scale score < 15); and/or (3) systolic blood pressure of 100 mm Hg or less. The qSOFA is best applied as an early warning sign of infection-induced organ dysfunction for use on the medical or

surgical floor, whereas the standard SOFA score has greater predictive power in the critical care setting. It is essential that clinicians recognize these early signs and symptoms because successful management of sepsis depends on early recognition and appropriate intervention. The mortality rate in sepsis increases with an increasing number of organ dysfunctions.

SEPTIC SHOCK

Septic shock occurs in up to 15% of patients with sepsis, and is defined as a hypotension requiring vasopressors to maintain a MAP of 65 or more and a serum lactate level of more than 2 mmol/L (18 mg/dL). The most common hemodynamic findings in early septic shock are a high cardiac output and a low systemic vascular resistance state. Myocardial performance is markedly diminished in septic shock. Without adequate intervention, circulating blood volume is continually lost into the interstitial space and intracellular locations, perpetuating systolic hypotension. Deterioration of myocardial performance, accompanied by diffuse vasoconstriction, marks the late refractory state of septic shock.

TABLE 42–5 The Sequential [Sepsis-Related] Organ Failure Assessment (SOFA) Score.¹

	Score				
	0	1	2	3	4
Respiration PaO ₂ /FiO ₂ , mm Hg (kPa)	≥ 400 (53.3)	< 400 (53.3)	< 300 (40)	< 200 (26.7) with respiratory support	< 100 (13.3) with respiratory support
Coagulation platelets, ×10 ³ /μL	≥ 150	< 150	< 100	< 50	< 20
Liver bilirubin, mg/dL(μmol/L)	< 1.2 (20)	1.2-1.9 (20-32)	2.0-5.9 (33-101)	6.0-11.9 (102-204)	> 12.0 (204)
Cardiovascular	MAP ≥ 70 mm Hg	MAP < 70 mm Hg	Dopamine < 5 or dobutamine (any dose) ²	Dopamine 5.1-15 or epinephrine ≤ 0.1 or norepinephrine ≤ 0.1 ²	Dopamine > 15 or epinephrine > 0.1 or norepinephrine > 0.1 ²
Central nervous system Glasgow Coma Scale Score	15	13-14	10-12	6-9	< 6
Renal creatinine, mg/dL(μmol/L) or	<1.2 (110)	1.2-1.9 (110-170)	2.0-3.4 (171-299)	3.5-4.9 (300-440)	> 5.0 (440)
Urine output, mL/d				< 500	< 200

The SOFA (Sepsis-related Organ Failure Assessment) score to describe organ dysfunction/failure. Intensive Care Med. 1996 Jul;22(7):707-710.
²Catecholamine doses are given as mcg/kg/min for 1 hour or more.

Acute Respiratory Distress Syndrome

The acute respiratory distress syndrome (ARDS) remains a major cause of morbidity and mortality in septic shock. Increased capillary permeability in these patients results in pulmonary edema, which manifests clinically as dyspnea and cough; standard radiographs will typically show bilateral, symmetrical alveolar opacities in all four quadrants. The initial diagnostic criteria for ARDS include the absence of clinical evidence of left atrial hypertension, the requirement for intubation and positive pressure ventilation, and a $\text{PaO}_2/\text{FiO}_2$ ratio of 200 or less. The new Berlin definition of ARDS simplifies the diagnostic criteria for ARDS and classifies the patients into three diagnostic and prognostic categories depending upon the severity of gas exchange based on the $\text{PaO}_2/\text{FiO}_2$ ratio (see Table 42–1). A detailed analysis of the Berlin definition of ARDS from a large patient database found that a $\text{PaO}_2/\text{FiO}_2$ ratio of between 200 and 300 mm Hg or less (classified as mild ARDS) was associated with a mortality rate $27 \pm 3\%$. Moderately severe ARDS with a $\text{PaO}_2/\text{FiO}_2$ ratio of 100 to 200 mm Hg or less was associated with a mortality rate of $32 \pm 3\%$. Severe ARDS manifest by a $\text{PaO}_2/\text{FiO}_2$ ratio 100 mm Hg or less is accompanied by a mortality rate of $45 \pm 2\%$.

Management of Septic Shock

The management of a patient with septic shock begins with prompt recognition of the condition and the rapid administration of appropriate antibiotic therapy as well as source control of infection. Attention is simultaneously given to failing organs with institution of measures including fluid resuscitation, vasopressors, blood transfusions, and inotropic agents as needed to maximize oxygen delivery. Patients with ARDS are managed with low tidal volume ventilator strategies to minimize damage induced by overstretching the alveoli. Consideration is also given to the use of low dose corticosteroids in cases of refractory septic shock. Reasonable glycemic control is utilized in effort to minimize septic complications. Guidelines for the initial management of sepsis are provided in the Surviving Sepsis Campaign guidelines.

Microbiologic Workup

A rapid systematic search for infection should include a thorough physical exam, review of pertinent radiographic studies, and microbiologic studies. The three most common sites of infection are the lung followed by infection in the abdomen and genitourinary tract. In approximately 30% of cases a causative organism and focus of infection is never found. Based upon history and physical exam imaging and culturing of normally sterile body sites should be done to define infection. In community-acquired pneumonia obtaining high-quality sputum samples for making an etiologic diagnosis is quite difficult. A rapid immunoassay that detects the C-polysaccharide from the cell wall of *Streptococcus pneumoniae* from the urine is clinically useful for the diagnosis of pneumococcal pneumonia. A similar urine immunoassay is available for *Legionella* spp. pneumonia. Two sets of blood cultures should be collected as soon as possible and preferably before starting antibiotics. If a central venous catheter is present, one blood culture should be drawn from the catheter and one from a peripheral venipuncture. A blood culture drawn from a central line that becomes positive 2 or more hours before a peripheral venipuncture drawn at the same time supports a diagnosis of a catheter-related bloodstream infection. In patients at high risk for candidemia, a beta-d-glucan assay should be obtained. This assay is often positive for 2 or more days before the blood culture grows *Candida* spp.

Appropriate Antibiotic Therapy

Numerous studies in patients with sepsis have demonstrated a survival advantage in patients who have received appropriate versus inappropriate antibiotic therapy. Furthermore, animal and human studies demonstrate a decrease in survival for each hour delay in the administration of antibiotic therapy from the onset of septic shock. Optimal antimicrobial therapy in sepsis depends on the site of infection, local susceptibility patterns, prior antimicrobial exposure, presence or absence of pregnancy, hepatic and renal function, and history of drug allergy. Suggested empiric antibiotic regimens for the different sites of infection are presented in Table 42–6. A propensity matched

TABLE 42–6 Suggested initial empiric antibiotic choices for sepsis.

Source of Infection	Antimicrobial Choice
Community-acquired pneumonia	Third-generation cephalosporin with a macrolide or respiratory fluoroquinolone. Use cefepime or piperacillin-tazobactam in place of third-generation cephalosporin if risk factors for Pseudomonas infection or MDR pathogens
Hospital-acquired pneumonia	Third- or fourth-generation cephalosporin or an extended-spectrum penicillin ± an aminoglycoside or a fluoroquinolone (or: carbapenems, β-lactam—β-lactamase inhibitor); add vancomycin or linezolid if MRSA suspected
Urinary tract infection	Extended-spectrum β-lactam agent ± aminoglycoside or fluoroquinolone). Use cefepime or a carbapenem if history of, or at risk for MDR organism
Intra-abdominal infection	A carbapenem or piperacillin-tazobactam as monotherapy or a third or fourth-generation cephalosporin or fluoroquinolone in combination with metronidazole
Neutropenic sepsis	Monotherapy with an antipseudomonal beta-lactam agent, such as cefepime, a carbapenem (meropenem), or piperacillin-tazobactam is recommended (add vancomycin when there is evidence of gram-positive infection or linezolid if MRSA or VRE suspected); add a triazole (voriconazole or fluconazole) or β-glucan inhibitor (eg, caspofungin or micafungin) if systemic fungal infection suspected
Necrotizing skin/soft tissue infection	Vancomycin and piperacillin-tazobactam ± clindamycin

MDR, multiple antibiotic drug resistant; MRSA, methicillin-resistant Staphylococcus aureus; VRE, vancomycin-resistant enterococcus.

analysis comparing monotherapy to combination therapy for sepsis favored combination therapy for both gram-positive and gram-negative infections in severely ill patients at increased risk of death (estimated mortality rate > 25%). Empiric treatment for methicillin-resistant Staphylococcus aureus (MRSA) depends upon the clinical context especially given the increasing incidence of infections due community-acquired, methicillin-resistant Staphylococcus aureus (CA-MRSA). Empiric antifungal therapy in patients with sepsis is not routinely recommended, but should be reserved for cases where patients have well-described risk factors for fungemia including a history of receiving multiple antibiotics for multiple days, the presence of a central venous catheter for TPN or hemodialysis, elevated beta-d-glucan levels or Candida spp. previously isolated from multiple anatomic sites. Initial antimicrobial therapy should be reconsidered at 72 hours and “deescalated” based upon the final culture and susceptibility data.

Optimizing Tissue Oxygenation

In the early phase of sepsis, an imbalance develops between tissue oxygen delivery and oxygen demand.

This can be diagnosed by laboratory testing of lactic acid levels. Rivers and colleagues performed a randomized, clinical trial to see if a protocolized algorithm of early goal directed therapy (EGDT) to meet a resuscitation goal of a central venous oxygen saturation of 70% decreased mortality in septic shock. In this study, patients with septic shock and lactic acidemia were randomized to either a standard therapy arm or EGDT arm. Patients in the EGDT group received crystalloid fluid boluses every 30 minutes in attempt to achieve a CVP of 8 to 12 mm Hg. If the mean arterial pressure remained less than 65 mm Hg vasopressors were then added. If following these maneuvers, the central venous O₂ saturation remained less than 70%, red cell transfusions were given to achieve a hematocrit of more than 30%. If these targets were still not met, dobutamine was then added. The in-hospital mortality was significantly lower in the EGDT group than the standard treatment group (30.5% vs 46.5%, P = 0009). This treatment strategy is now widely utilized and is generally followed in the recent 2013 sepsis guidelines. However, three subsequent, large, randomized trials have failed to confirm a clear survival

advantage to EGD_T versus usual care in the emergency resuscitation of patients in septic shock.

Fluid Resuscitation

Debate continues regarding the appropriateness of colloid versus crystalloid fluids. The lack of clear evidence of benefit of colloid agents (eg, albumin, dextran, and plasma expanders) and their high cost have generally resulted in the use of saline solutions for volume expansion.

Vasopressor Therapy

Failure to improve patient hemodynamics with fluids alone often necessitates the use of vasopressor agents to reestablish adequate tissue perfusion. Dopamine, epinephrine, norepinephrine, phenylephrine, and vasopressin have been used to reverse hypotension in the setting of septic shock. The use of any of these agents in septic shock carries with it certain risks and should be reserved for patients with significant hemodynamic instability that is unresponsive to fluid therapy. The clinical target of vasopressors to maintain organ perfusion is a mean arterial pressure of more than 65 mm Hg. Results of both individual studies and a meta-analysis have revealed that the use of dopamine is associated with a higher mortality and a higher incidence of arrhythmias than norepinephrine. As such, norepinephrine is now considered the agent of first choice for septic shock. Dobutamine remains the inotropic agent of first choice in septic shock in patients with low cardiac output despite adequate fluid resuscitation.

Low-Dose Corticosteroid Therapy for Septic Shock

The value of corticosteroids in the treatment of sepsis have been the subject of a debate for greater than fifty years. Studies have also suggested that a state of relative adrenal insufficiency and glucocorticoid resistance occurs during sepsis and is associated with a poor outcome. A study by Annane observed relative adrenal insufficiency, defined as an increase in serum cortisol less than 9 mg/dL 60 minutes after receiving 250 mg of synthetic ACTH in patients with septic shock. In a clinical study in patients with

vasopressor-dependent refractory septic shock to receive either 50 mg of hydrocortisone every 6 hours and 50 mg/day of fludrocortisone improved survival over placebo treatment. A large follow-up study failed to confirm the benefit of low-dose corticosteroids, with the possible exception of patients with refractory septic shock. The current recommendation is to consider corticosteroids (≤ 200 mg of hydrocortisone/day) in the subpopulation with refractory septic shock. Treatment should be given for at least 5 days followed by a taper to prevent rebound hypotension.

Blood Transfusions

The threshold for blood transfusions in improving the oxygen-carrying capacity of blood is a matter of ongoing research. A large Canadian study, the TRICC trial (Transfusion requirements in Critical Care) showed that maintaining a hemoglobin (Hgb) level of 7 to 9 gm/dL and setting a transfusion threshold as low as 7 gm/dL in volume-resuscitated patients is not associated with a worse outcome than maintaining an Hgb of more than 10 gm/dL. The hemoglobin level may need to be maintained at a higher level include severe coronary artery disease and severe hypoxemia.

Glycemic Control

Reasonable glycemic control in sepsis is now considered glucose control (targeted around 150 mg/dL) is now recommended in patients with sepsis-induced glucose intolerance. Large swings on blood glucose levels are to be avoided and hypoglycemia can be particularly hazardous.

Infection Control

Patients with severe sepsis are at risk for the development of new infections and superinfections. In patients on mechanical ventilation, elevating the head of the bed by 30 to 45 degrees limits the risk of aspiration and ventilator-associated pneumonia. Carts containing all the materials necessary for sterile insertion of central venous catheters should be used and maintained in all ICUs. Universal MRSA decolonization of ICU patients with nasal mupirocin and chlorhexidine baths has been shown to decrease the incidence of bloodstream infections.

Experimental Therapies for Septic Shock

Despite the failure of many agents in the past, studies of additional experimental treatments continue. Late-stage therapies are targeting sepsis-induced DIC and patients with elevated endotoxin activity. Multiple failures using a variety of anti-inflammatory compounds have led to a renewed appreciation of the immunoparalysis of sepsis. The future therapy of sepsis will likely resemble cancer chemotherapy with personalized combinations of agents being used to target each patient's unique situation and needs.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Antimicrobials in the ICU

Perminder Gulani, MD; Julie Chen, PharmD, BCPS;
and Adam Keene, MD, MS

KEY POINTS

- 1 Because therapeutic delay has been clearly shown to increase mortality, prompt empiric broad-spectrum antimicrobial therapy is crucial in patients with shock and new organ dysfunction thought secondary to infection.
- 2 Overuse of antimicrobials in the ICU is common and is associated with multiple adverse drug reactions, superinfections and the development of antimicrobial resistance; antimicrobial therapy should be tailored as soon as possible and courses of therapy should not be prolonged unnecessarily.
- 3 Beta-lactams are the most important antibacterial agents used in the ICU; allergic reactions are the most common adverse effects but are frequently misreported so the risks of such reactions must always be weighed against the importance of these agents for severe bacterial infections.
- 4 The aminoglycosides are potent agents against gram-negative bacteria but their utility is limited by frequent misdosing due to concerns of nephrotoxicity; extended dosing intervals can be helpful in maximizing efficacy and minimizing toxicity.
- 5 The fluoroquinolones have activity against a variety of bacterial infections in the ICU; they are generally well tolerated but are considered second-line agents for a number of severe sepsis syndromes.
- 6 Vancomycin, linezolid, and daptomycin are important agents for resistant gram-positive infections in the ICU. Their utility varies by the site of primary infection.
- 7 Azithromycin and doxycycline are particularly useful for atypical bacterial infections in the ICU and are generally well tolerated. Metronidazole and clindamycin are useful primarily for coverage of anaerobic infections in the ICU.
- 8 Tigecycline and polymyxin B/colistin are used mainly for resistant gram-negative infections in the ICU; use of the former is limited by lack of potency and the latter is limited by high potential for nephrotoxicity.
- 9 The three classes of antifungals used in the ICU are the polyenes, the azoles, and the echinocandins. Polyenes are broad spectrum but nephrotoxic; azoles have variable coverage but resistance can be a problem; echinocandins are excellent anticandidal agents and are generally well tolerated.
- 10 The nucleoside analogues are the primary agents used to treat herpes viruses in the ICU; their efficacy is variable and they may cause hematologic and renal toxicity.
- 11 The neuraminidase inhibitors are important agents that may improve the outcome of influenza virus infections in the ICU.

INTRODUCTION

The principles used to guide antimicrobial therapy in all patients can be applied to the critically ill patients, with some modification. Patient characteristics including environmental history, immune status, prior antimicrobial exposure, and prior culture results are essential in determining likely organisms and appropriate empiric therapy. In patients who develop infection after hospital admission, knowledge of common local institutional pathogens and their sensitivity patterns is important. Source identification and control are crucial, although imaging tests may be limited by patient instability and organ failure. As discussed further in the Chapter “Pharmacology in Critical Illness,” the efficacy and toxicity of antimicrobial agents can be profoundly affected by the alterations in tissue perfusion, volume of distribution, serum protein levels, and renal and hepatic function that occur in the critically ill patients.

In ICU patients with new onset of shock and organ dysfunction thought secondary to infection, prompt empiric broad-spectrum antimicrobial therapy is crucial. Each hour of delay in adequate antimicrobial therapy after the onset of hypotension has been associated with a mean decrease in survival of 7.6%.¹ Although the common infectious syndromes encountered in the ICU are discussed elsewhere, suggested empiric antimicrobial therapy for non-immunocompromised patients based on suspected source is provided in [Table 43–1](#).

Unfortunately, antimicrobials are also the most unnecessarily prescribed medications in the ICU. Antimicrobial overuse has numerous deleterious effects. Allergic reactions, drug fever, and nephrotoxicity are common. In addition, antibiotic overuse has been clearly linked to the development and transmission of multidrug resistant (MDR) organisms.² Finally, the development of antibiotic-associated *C. difficile* colitis is a particular danger to ICU patients that has been worsened by the recent emergence of hypervirulent strains.³

A few strategies may help to strike a balance between the seemingly opposing recommendations to provide broad antimicrobial coverage for septic critically ill patients and to avoid antimicrobial overuse in the ICU. While it is important to provide

empiric therapy that covers all likely pathogens in the critically ill patient, it is also imperative to step down the antimicrobial regimen as much as possible once culture results are available. Because standard culture techniques have limited sensitivity, it is sometimes necessary to continue broad empiric therapy even in the face of negative cultures. Biomarkers such as procalcitonin tend to become markedly elevated in the face of serious bacterial infections, and normal levels may be useful in rapidly ruling out such a process.⁴ Unfortunately, a myriad of non-infectious critical illnesses cause these nonspecific biomarkers to rise as well. Because of this, they are usually unable to safely rule out bacterial infections in the acutely critically ill patients and may actually increase the use of antibiotics when they are used to drive antimicrobial initiation.⁵ Molecular tests to detect the presence of invasive pathogens are just beginning to show clinical utility, and in the future may greatly increase our ability to rapidly and safely narrow antimicrobial therapy.

When narrowing antimicrobial coverage it is important to understand that antibiotic spectrum and antibiotic potency are distinct concepts, and that many of the antimicrobials that are reserved to treat MDR infections have both suboptimal efficacy and increased toxicity. For health-care-associated pneumonia (HCAP) caused by pathogens other than methicillin-resistant *Staphylococcus aureus* (MRSA) and nonlactose fermenting gram-negative rods, there is now adequate evidence that antibacterials may be stopped after 8 days, thus decreasing overall antibiotic exposure.⁶ Properly organized antibiotic stewardship programs can help clinicians to rationally utilize antimicrobials and have been shown to safely reduce antimicrobial overuse in the ICU.⁷

ANTIMICROBIAL AGENTS COMMONLY USED IN THE ICU

Due to space limitations several agents that are significant but infrequently used will not be discussed here. These include the antibacterial agents quinupristin/dalfopristin and telavancin, the antiviral agents cidofovir and ribavirin, the antifungal agents itraconazole and pentamidine, and the antiparasitic agents albendazole, ivermectin, artesunate, and quinine.

TABLE 43–1 Suggested empiric antimicrobial therapy for adult patients with newly acquired severe sepsis/septic shock.

Suspected Source	Empiric Therapy by Patient Type		Comments
	Community Acquired/ Antibiotic Naive	Health Care Associated/Prior Antibiotic Exposure	
Lung	(A) Ceftriaxone plus azithromycin or an antistreptococcal quinolone plus (B) Vancomycin or linezolid	(A) Piperacillin/tazobactam or cefepime or imipenem/cilastatin plus (B) An aminoglycoside or ciprofloxacin plus (C) Vancomycin or linezolid	Consider empiric antiviral therapy (ie, oseltamivir) during seasonal outbreaks.
Heart/intravascular catheter/ bloodstream/ unknown source	(A) Vancomycin plus (B) Ceftriaxone	(A) Vancomycin plus (B) Piperacillin/tazobactam or cefepime or imipenem/cilastatin plus/minus (C) An aminoglycoside	Consider echinocandins if patient with risk factors for candidemia. Consider rifampin if endovascular prosthesis present. Catheter removal whenever possible, particularly for patients in shock.
Intra-abdominal	(A) Cefoxitin, ertapenem, moxifloxacin, or ticarcillin/clavulanate or (B) Ceftriaxone plus metronidazole or (C) Ciprofloxacin plus metronidazole	(A) Imipenem/cilastatin or piperacillin/tazobactam or (B) Cefepime plus metronidazole plus/minus (C) An aminoglycoside	Empiric antipseudomonal therapy may be considered in severely ill patients with community-acquired infections. Always consider C. difficile.
Skin and soft tissue	(A) Vancomycin plus (whether diabetic or vasculopath) (B) Piperacillin/tazobactam and (if concern for toxic shock syndrome) clindamycin	(A) Vancomycin plus (whether diabetic or vasculopath) (B) Piperacillin/tazobactam and (if concern for toxic shock syndrome) clindamycin	For community-acquired infections, environmental exposures (to water, animals, plants, etc) must be considered.
Genitourinary	(A) Ceftriaxone or (B) Ampicillin/sulbactam	(A) Cefepime or (B) Piperacillin/tazobactam or (C) Imipenem	Consider adding an aminoglycoside to any patient in shock or with a history of recurrent infections.
Central nervous system	(A) Ceftriaxone (2 grams every 12 hours) plus (B) Vancomycin plus (C) Ampicillin (if age > 60 years)	(A) Cefepime or imipenem/cilastatin plus (B) Vancomycin	High-dose acyclovir should be added if suspicion of encephalitis. Metronidazole should be added if suspicion of brain abscess.

These recommendations do not take into account all clinical scenarios and are not intended for immunocompromised patients, pregnant women, and travelers.
Knowledge of predominant local pathogens and their sensitivity profiles may alter optimal empiric therapeutic regimens.
Appropriate cultures should be drawn before antimicrobials are administered.
Doripenem or meropenem may be substituted for imipenem/cilastatin.

Antibacterials

β -Lactams

The β -lactam group includes the penicillins, cephalosporins, carbapenems, and monobactams. All β -lactams share a common mechanism of action: inhibition of synthesis of the bacterial peptidoglycan cell wall by binding to variety of penicillin-binding proteins (PBPs). All β -lactams are bactericidal and demonstrate time-dependent killing; time for which drug levels exceed the minimum inhibitory concentration (MIC) correlates best with bacterial eradication. β -lactams can be inactivated by bacterial β -lactamases, a process that can be prevented by combining them with β -lactamase inhibitors such as sulbactam, clavulanate, and tazobactam. Bacterial resistance against the β -lactam antibiotics continues to increase at a dramatic rate. Mechanisms of resistance include not only production of β -lactamases but also alterations that cause decreased entry or active efflux of antibiotic and acquisition of novel PBPs.

Penicillins

Natural penicillins (penicillin G)—The use of penicillin G in the ICU is limited to treatment of proven infection due to sensitive organisms. It is active against most streptococci but penicillin-resistant *S. viridans* and *S. pneumonia* are becoming more common. It is not active against staphylococci. It continues to be highly active against *Neisseria*, *Clostridia*, *Corynebacterium*, *Treponema*, *Leptospira*, and *Actinomyces* species as well as *Treponema pallidum* and *Borrelia burgdorferi*.

Antistaphylococcal penicillins (methicillin, oxacillin, and nafcillin)—The antistaphylococcal penicillins were specifically developed to treat infections due to *S. aureus*. They are the preferred drugs for infections with methicillin-sensitive strains (MSSA) because their use has been associated with decrease mortality compared to vancomycin.⁸ However, in areas where MRSA is broadly prevalent these agents should not be used alone for empiric treatment of suspected *S. aureus* infections.⁹

Aminopenicillins (ampicillin and ampicillin/sulbactam)—Ampicillin is the drug of choice for infections due to *Listeria monocytogenes* and those caused by sensitive strains of *Enterococcus*. Although it has activity against some community-acquired gram-negative organisms, many strains of

H. influenza, *E. coli*, *Enterobacter*, and *Klebsiella* species are resistant, as are *Serratia*, *Pseudomonas*, and *Acinetobacter* species. Ampicillin–sulbactam has a wide range of antibacterial activity that includes gram-positive and gram-negative aerobic and anaerobic bacteria. However, the drug is not active against *Pseudomonas* and pathogens producing ESBLs. In addition, it is no longer recommended as an empiric treatment for community-acquired intra-abdominal infections due to a high prevalence of resistant *E. coli*.¹⁰ One of the specific advantages of this agent is the inherent activity of sulbactam against *Acinetobacter baumannii*, making it a valuable option against MDR isolates.¹¹

Extended spectrum penicillins (piperacillin–tazobactam and ticarcillin–clavulanate)

Piperacillin–tazobactam and ticarcillin–clavulanate are β -lactam/ β -lactamase combinations with a broad spectrum of antibacterial activity. Their gram-positive activity includes MSSA and some strains of *Enterococcus*. They have good activity against many nosocomial gram-negative organisms including most strains of *Pseudomonas*, but are not effective against ESBL-producing *E. coli* and *Klebsiella* species. Resistance may develop during therapy for *Enterobacter* and other organisms that produce inducible β -lactamases, so they are not the preferred drugs for serious infections due to these organisms. They are frequently included as part of an empiric regimen for critically ill patients with new-onset sepsis. Piperacillin–tazobactam, in particular, has been shown to be effective in the treatment of patients with intra-abdominal infections, HCAP, complex skin and soft tissue infections (cSSTIs), and febrile neutropenia.¹²

Cephalosporins

The cephalosporins are commonly used in the ICU. They are classified into generations, each having been developed to combat specific groups of resistant organisms.

First-generation cephalosporins (cefazolin)

Cefazolin has good activity against β -hemolytic streptococci, MSSA, and many community-acquired gram-negatives. It is no longer a preferred drug for empiric treatment of skin and soft tissue infections due to the increased prevalence of community- and hospital-acquired MRSA.

Second-generation cephalosporins (cefoxitin, cefotetan, and cefuroxime)—These have broader spectra than the first-generation agents, covering most strains of *E. coli*, *Enterobacter*, *Proteus*, and *Klebsiella* species. They are less active than the first-generation agents against gram-positives, but both cefoxitin and cefotetan have good anaerobic activity. The use of these agents in the ICU is generally limited to community-acquired intra-abdominal infections. Like nearly all cephalosporins, they are not active against *Enterococcus* species.

Third-generation cephalosporins (ceftriaxone and ceftazidime)—Ceftriaxone has good activity against *Pneumococcus*, β -hemolytic streptococci, and MSSA. Its activity is more variable against *S. viridans* and it has no activity against MRSA. It is highly active against *Haemophilus*, *Moraxella*, *Neisseria*, *Salmonella*, and *Shigella* species. However, like other third-generation cephalosporins, it has variable activity against most *Enterobacteriaceae*. It is not active against *Acinetobacter*, *Pseudomonas*, or *Stenotrophomonas maltophilia*. Extensive data from randomized clinical trials confirm the efficacy of ceftriaxone in treatment of serious and difficult to treat community-acquired infections including pneumonia, pyelonephritis, and (at high dose) meningitis. Ceftriaxone is currently recommended as a first-line empirical treatment option (with the addition of a macrolide) for community-acquired pneumonia (CAP) in both Europe and the United States. Ceftazidime has good coverage against gram-negatives including *Pseudomonas*. However, its gram-positive activity is poor. In the past it was used extensively for neutropenic fever and for meningitis related to neurosurgical procedures, but its clinical niche has been greatly diminished by the development of cefepime.

Fourth-generation cephalosporins (cefepime)—Cefepime is a broad-spectrum agent with activity against gram-positive organisms such as *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and MSSA. It also has good activity against nosocomial gram-negative bacteria including many strains of *Pseudomonas*, *E. coli*, and *Klebsiella*. It has poor activity against agents such as *Stenotrophomonas maltophilia*, *Acinetobacter*, and gram-negative anaerobes. Although ESBL-producing organisms are frequently sensitive to this agent in vitro, the

clinical efficacy of cefepime in treating serious infections due to these organisms may be inferior to that of the carbapenems. Cefepime is a recommended agent for empiric treatment of HCAP, neutropenic fever, and central nervous system (CNS) infections associated with neurosurgical procedures.

Fifth-generation cephalosporins (ceftaroline)—Ceftaroline, unlike other cephalosporins, possesses bactericidal activity against resistant gram-positive pathogens including MRSA and resistant pneumococci. It also covers many gram-negative pathogens. However, it has poor activity against *Pseudomonas*, *Acinetobacter*, and ESBL-producing organisms. Approved indications for ceftaroline include cSSTIs and CAP.

Carbapenems (Imipenem/Cilastatin, Meropenem, Doripenem, and Ertapenem)

Carbapenems are broad-spectrum agents that are frequently reserved for critically ill patients with suspected or proven infection due to resistant nosocomial organisms. They are active against organisms that produce inducible amp-C β -lactamases as well as those that produce ESBLs. With the exception of ertapenem, they are useful in the treatment of *Pseudomonas* and *Acinetobacter* infections. However, they are not active against MRSA, *Enterococcus faecium*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia*. Because of their broad range of activity, imipenem–cilastatin, meropenem, and doripenem are indicated for complicated intra-abdominal infections, HCAP, neutropenic sepsis, and CNS infections related to neurosurgical procedures. Ertapenem is a newer analogue and has a prolonged half-life. It has a narrower spectrum than the other carbapenems and is not active against *Pseudomonas* or *Acinetobacter* species. It is indicated for CAP, urinary tract infections (UTIs), and intra-abdominal infections.

Monobactams (Aztreonam)

Aztreonam has broad aerobic gram-negative activity but lacks gram-positive and anaerobic activity. Its spectrum includes *Pseudomonas* but it is ineffective against ESBL-producing organisms. The majority of *Acinetobacter* and *S. maltophilia* strains are resistant. Resistant strains of *P. aeruginosa* frequently emerge during aztreonam monotherapy.

Aztreonam has minimal cross-allergenicity with the other β -lactams, with the exception of ceftazidime due to structural similarity. Aztreonam is frequently used in treating patients with severe β -lactam allergy, usually in combination with other agents such as vancomycin or an aminoglycoside.

Adverse Effects of β -Lactams

Allergic reactions are the most common serious adverse effects noted with the β -lactams. These may manifest as maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens–Johnson syndrome, and anaphylaxis. The reported overall incidence of such reactions to the penicillins is 0.7% to 10%. Historical reports of penicillin allergy may be inaccurate; only about 20% of patients with a reported penicillin allergy have such an allergy confirmed on skin testing.¹³ There is cross-allergenicity between all the forms of penicillin. Studies have reported 1% to 20% cross-allergenicity between penicillins, cephalosporins, and carbapene-ms. Persons who have had a non-life-threatening reaction to one class of β -lactam may receive a trial agent of a different class for appropriate empiric or definitive therapy. For patients with a history of life-threatening allergy, in whom a β -lactam agent is necessary, desensitization may be required. Other serious adverse effects of the β -lactams include interstitial nephritis, transaminitis, bone marrow suppression, and lowering of the seizure threshold.

Aminoglycosides (Gentamicin, Amikacin, and Tobramycin)

Aminoglycosides are bactericidal agents which bind irreversibly to the 30S subunit of the bacterial ribosome. They have excellent activity against gram-negative aerobic bacteria. They are ineffective against gram-positive and anaerobic bacteria. However, in the presence of a cell-wall active antibiotic, they may have a synergistic effect against aerobic gram-positive organisms. These agents exhibit concentration-dependent killing; bactericidal activity is maximized when the peak serum concentration is 8 to 10 times above the MIC. They also have a significant postantibiotic effect. These two pharmacodynamic properties provide the rationale for high-dose, extended-interval dosing of aminoglycosides.¹⁴

High dosing (5–7 mg/kg for gentamicin or tobramycin and 15–20 mg/kg for amikacin) assures adequate peak concentrations; this eliminates the need to check peak serum levels. Extended dosing intervals may also limit nephrotoxicity by allowing time for renal recovery. Trough concentrations should be confirmed to be essentially zero when this strategy is used.

The most common indications for the primary use of aminoglycosides in the critically ill patient are complicated UTIs, complicated intra-abdominal infections (in addition to an agent with anaerobic activity), and gram-negative bacteremia. These agents are also recommended in combination with an antipseudomonal β -lactam as empiric therapy for patients with HCAP and as definitive therapy for patients with confirmed pseudomonal bacteremia. Synergistic doses of gentamicin (1–1.5 mg/kg every 8–12 hours for patients with normal renal function) are recommended for combination therapy for enterococcal endocarditis, staphylococcal or streptococcal endocarditis in the presence of a prosthetic valve, and streptococcal endocarditis in the presence of intermediate penicillin resistance.

Aminoglycosides are inactivated in acidic, anaerobic environments such as abscesses and have poor lung tissue penetration. Inhaled aminoglycosides may overcome this latter limitation, although clinical data to support this mode of administration are limited.

The primary toxicities of aminoglycosides are dose-related nephrotoxicity, ototoxicity, and neuromuscular paralysis. With the exception of the ototoxicity, these adverse reactions may be reversible after drug discontinuation. Elevated serum trough levels, hypotension, concurrent nephrotoxic drugs, female sex, and liver disease have been shown to increase the risk of aminoglycoside-induced nephrotoxicity. These agents should be used with caution in patients receiving neuromuscular blocking agents and in patients with neuromuscular disease.

Fluoroquinolones (Ciprofloxacin, Levofloxacin, and Moxifloxacin)

These bactericidal agents act by inhibiting bacterial DNA gyrase and/or topoisomerase-IV, resulting in damage to bacterial DNA and cell death. Quinolones exhibit concentration-dependent killing.

Bactericidal activity becomes more pronounced as the serum drug concentration increases to roughly 30 times the MIC. Ciprofloxacin, a second generation quinolone, has expanded gram-negative activity and atypical pathogen coverage. It is distinguished by its potency against *Pseudomonas*, for which it is the most useful fluoroquinolone for systemic therapy. It is a valuable agent for treatment of complicated UTIs, prostatitis, and as part of combination therapy for HCAP. However, it is not a preferred agent for CAP because of poor pneumococcal susceptibility. Levofloxacin and moxifloxacin, the third generation quinolones, are characterized by clinically useful antibacterial activity against *Chlamydia*, *Legionella*, *Mycoplasma*, and streptococci including penicillin-resistant pneumococci. They are recommended first-line agents for treatment of CAP, either alone or in combination with extended-spectrum cephalosporin. Moxifloxacin does not concentrate in the urine and thus should not be used for UTIs. Fluoroquinolones are generally well tolerated. Adverse effects include gastrointestinal and CNS symptoms as well as dysglycemia and QT-interval prolongation. Achilles tendon rupture is a rare adverse effect of fluoroquinolones.

Miscellaneous Antibacterials

Vancomycin—The glycopeptide antibiotic vancomycin acts by disrupting the biosynthesis of peptidoglycan, the primary structural polymer of gram-positive cell walls. Vancomycin exhibits time-dependent bactericidal activity. It is active against number of aerobic and anaerobic gram-positive bacteria. Vancomycin is a first-line agent for suspected or proven methicillin-resistant strains of coagulase-negative and coagulase-positive staphylococcal infections, including bacteremia, endocarditis, pneumonia, cSSTI, osteomyelitis, septic arthritis, and CNS infections. It should not be used to treat MSSA infections because it is inferior to β -lactams for these infections. Vancomycin is a drug of choice for infections caused by penicillin-resistant streptococci and enterococci. It is recommended as initial therapy for cases of proved, suspected, or possible pneumococcal meningitis, in combination with a third-generation cephalosporin. Oral vancomycin is the drug of choice for the treatment of severe *C. difficile* enterocolitis.

Unfortunately, the prevalence of vancomycin resistance is on the rise among *Enterococcus* species and *S. aureus*. Although plasmid-mediated vancomycin resistance remains rare among *S. aureus*, intermediate sensitivity due to the production of a thickened cell wall is an increasing problem. Intermediate resistance may develop during therapy, so MICs should be rechecked whenever cultures remain persistently positive. *S. aureus* strains with MICs more than 1.5 mcg/mL have been associated with poorer response rates. In addition, strains that display variable sensitivity to vancomycin (heteroresistance) have been reported and associated with treatment failure.¹⁵

Rapid infusion of vancomycin can lead to histamine-release-induced “red man” syndrome. Clinical signs and symptoms include pruritus, erythema and flushing of the upper torso, angioedema, and (occasionally) hypotension. Slow infusion (over at least 2 hours) and prophylactic antihistamines may prevent this syndrome. Nephrotoxicity is much less common with modern formulations of the drug but may occur with persistently elevated trough levels (>20 mcg/mL) or with concurrent aminoglycoside therapy. These are also the primary risk factors for ototoxicity, which may be irreversible. Vancomycin-induced neutropenia is rare.

Linezolid—Linezolid is an oxazolidinone antibiotic which acts in a bacteriostatic manner by blocking protein synthesis via the 50S ribosomal subunit. It is active against gram-positive aerobes including *S. aureus* (MSSA, MRSA, VISA, and VRSA), streptococci, and enterococci including vancomycin-resistant strains (VRE). Linezolid is recommended as an initial or alternative therapy for patients with cSSTIs, osteomyelitis, septic arthritis, meningitis, and brain abscesses. In one clinical trial, patients with confirmed MRSA pneumonia treated with linezolid had higher clinical response rates than those who received vancomycin (57% vs 46%).¹⁶ Thus it is a reasonable choice for initial empiric MRSA coverage in patients with HCAP. However, because linezolid is a bacteriostatic agent, it is generally not recommended as first-line therapy for endovascular infections. Some gram-positive organisms have developed resistance to linezolid, but fortunately this is currently at low prevalence (<1%). Irreversible peripheral neuropathy and optic neuritis have

been described with prolonged use. Other adverse effects with extended use include thrombocytopenia and lactic acidosis. Linezolid is a weak monoamine oxidase inhibitor. Concurrent serotonergic medications are contraindicated.

Daptomycin—Daptomycin, a cyclic lipopeptide antibiotic, exerts its bactericidal effects by binding to, damaging, and causing depolarization of the cell membrane of gram-positive bacteria. Its antibacterial spectrum covers staphylococci (MSSA, MRSA, VISA, and VRSA), streptococci, and enterococci including VRE. Daptomycin is indicated for bacteremia and endocarditis caused by these organisms, either as initial therapy or in cases of reduced vancomycin sensitivity or clinical failure. It is also recommended as an initial or alternative therapy for cSSTIs. Its antibacterial activity is inhibited by pulmonary surfactant, and it should not be used for treatment of pneumonia. The prevalence of daptomycin resistance in clinical isolates of *S. aureus* appears to be low (0.3%). Unfortunately, the prevalence of daptomycin resistance appears to be increased in those MRSA isolates with reduced vancomycin sensitivity. Rhabdomyolysis is the primary toxicity of the drug. Concurrent use of statins may increase the risk of this toxicity.

Tigecycline—Tigecycline, a glycylcycline antibiotic closely related to the tetracyclines, has a broad spectrum of activity. It is a bacteriostatic agent that binds to the bacterial 30S ribosomal subunit. Tigecycline covers gram-positive and gram-negative aerobes and anaerobes as well as atypical species. It is active against MRSA, VRE, ESBL-producing organisms, inducible ampC producing organisms, KPC organisms, *Stenotrophomonas*, and *C. difficile*. However, it is inherently inactive against *Pseudomonas* species and is less effective against *Proteus* and *Providencia* species. Although it is effective in vitro against *Acinetobacter* isolates, there is increasing concern with clinical-treatment failures. It is FDA approved for the treatment of CAP.

Tigecycline is a bacteriostatic agent and does not maintain adequate serum concentrations for the treatment of bloodstream infections. In addition, in 2013 the FDA issued a black box warning based on postmarketing analyses suggesting an increased risk of death in patients with pneumonia who receive tigecycline as compared with other antimicrobials.¹⁷ Thus, this agent should only be used when no

other antimicrobial options are available. The most frequent side effects associated with the use of tigecycline are gastrointestinal.

Azithromycin—Azithromycin belongs to the macrolide class of antibiotics, which inhibit protein synthesis by binding to the 50S subunits of bacterial ribosomes. It is active against *S. pneumonia* and *Hemophilus* as well as atypical pneumonia pathogens including *Legionella*, *Chlamydia*, and *Mycoplasma*. It is recommended in combination with ceftriaxone for the empiric treatment of CAP. Major toxicities of azithromycin include hepatic injury and QT-interval prolongation.

Doxycycline—Doxycycline is the most commonly used tetracyclines which function by binding to the 30S ribosomal subunit. It is a bacteriostatic agent that is active against many aerobic and atypical pathogens including *Rickettsia*, *Borrelia*, *Chlamydia*, and *Mycoplasma*. Due to high rates of pneumococcal resistance in the United States it is not a drug of choice for CAP.

Clindamycin—Clindamycin works primarily by binding to the 50S ribosomal subunit of bacteria and disrupting protein synthesis. It is active against gram-positive organisms including streptococci and *S. aureus* including some strains of community-acquired MRSA. It has excellent anaerobic activity, although some gram-negative anaerobes such as *Bacteroides* show resistance. It is also frequently used to decrease superantigen production in toxic shock syndromes due to β -hemolytic streptococci and *S. aureus*. Clindamycin use increases the risk of *C. difficile* colitis.

Metronidazole—Metronidazole is a bactericidal agent that acts by fatal destabilization of the DNA helix. It is active against most anaerobic gram-negative bacilli including *Bacteroides*, *Prevotella*, *Fusobacterium*, and *Clostridium* species but has minimal activity against many anaerobic gram-positive organisms. It is also active against some protozoa including *Entamoeba* and *Giardia*. Oral metronidazole is the drug of choice for treatment of mild to moderate *C. difficile* colitis. Because of good CNS penetration, it is empirically included to cover anaerobes in the setting of brain abscess. It is a preferred agent for intra-abdominal and genital infections. Taste disturbances and peripheral neuropathy are the major side effects of metronidazole.

Trimethoprim/sulfamethoxazole—Trimethoprim/sulfamethoxazole (TMP-SMX) is available in a fixed combination of 1:5 and works by sequential blockade of microbial folic acid synthesis. The use of TMP-SMX in the ICU is often limited to patients known to have susceptible organisms or to immunocompromised patients with suspected *Pneumocystis jirovecii* infections. TMP-SMX is also a first-line treatment for infections caused by the gram-negative bacilli *Stenotrophomonas maltophilia* and *Burkholderia cepacia*. Skin rashes, bone marrow suppression, interstitial nephritis, hyperkalemia, and aseptic meningitis are major side effects.

Polymyxin B and colistin (polymyxin E)—Polymyxins are cationic polypeptides which were originally discovered in 1950s. The use of polymyxins decreased over the next few decades because of their toxicity profile and the development of newer, more tolerable agents. However, recently they have been reintroduced for the treatment of MDR gram-negative bacilli infections. These agents interact with the anionic lipopolysaccharide molecules in the outer membrane of gram-negative bacteria, ultimately resulting in loss of membrane integrity and cell death. Polymyxin B and colistin have identical spectra, and are active against most aerobic gram-negative bacilli including MDR *Pseudomonas aeruginosa*, *Acinetobacter* species, *Stenotrophomonas maltophilia*, ESBL-producing organisms such as *Klebsiella* species and *E. coli*, and carbapenemase-producing *Enterobacteriaceae*. They are not active against *Serratia* and *Proteus* species. They are inherently inactive against gram-positive bacteria and anaerobes. Reasonable clinical cure rates (close to 70%) have been reported in critically ill patients treated with the polymyxins for pneumonia and bacteremia caused by MDR strains of *Pseudomonas* and *Acinetobacter*.¹⁸ Although clinical data is limited, these agents may also be administered intrathecally for meningitis and in aerosolized form for pneumonia in cases of resistant or refractory disease. The most common toxicities of the polymyxins are dose-dependent nephrotoxicity and neurotoxicity. In the past, reported incidences of nephrotoxicity were as high as 58%. However, recent data suggest an incidence of 10%. Neurotoxicity occurs in about 5% of patients and includes perioral paresthesias, ataxia, visual disturbances, confusion, vasomotor instability, and neuromuscular blockade.

Antifungals

Polyenes (Amphotericin B Deoxycholate, Liposomal Amphotericin B, Amphotericin B Lipid complex, and Amphotericin B Colloidal Dispersion)

The polyenes act by binding to sterols in the fungal cell membrane, increasing permeability and precipitating cell death. The various formulations of amphotericin B have the broadest antifungal spectra, with resistance among only a few significant species including *Aspergillus terreus* and *Candida lusitanae*. Amphotericin B in combination with flucytosine continues to be the mainstay of initial treatment of CNS or disseminated cryptococcosis. It has been replaced by voriconazole as the first-line agent for treatment of invasive aspergillosis. It is the mainstay of treatment against all forms of invasive mucormycosis as well as against life-threatening forms of histoplasmosis, blastomycosis, and coccidiomycosis. Infusion of amphotericin B is commonly associated with severe febrile reactions, generalized malaise, and gastrointestinal symptoms. These can be minimized by prophylactic antihistamines, antipyretics, and antiemetics. Rapid infusion of amphotericin B has been reported to precipitate life-threatening hyperkalemia and cardiac arrhythmias; therefore, the daily dose of amphotericin B should be infused over 2 to 6 hours. Dose-dependent nephrotoxicity is the major limitation of amphotericin B, and about 80% of the patients receiving the deoxycholate form of the drug show some degree of renal impairment. It manifests as azotemia, decreased urinary concentration ability and a distal renal tubular acidosis with profound potassium and magnesium wasting. The most effective preventative measure is preinfusion and postinfusion crystalloid administration. Although higher doses of the liposomal forms are necessary to achieve equivalent serum levels, they have been shown to be less nephrotoxic than amphotericin B deoxycholate. They are used routinely in critically ill patients despite their higher cost. Anemia is common with long-term amphotericin B therapy. Hepatotoxicity is rare but may be severe.

Azoles (Fluconazole, Voriconazole, and Posaconazole)

Azoles inhibit the enzyme lanosterol 14- α -demethylase, which converts lanosterol to ergosterol,

a key component of cell membranes. In areas with a low prevalence of azole-resistance, fluconazole is a first-line empiric therapy for candidal infections in non-neutropenic, azole-naïve hemodynamically stable patients. It has no activity against *Candida krusei* and up to 30% of *Candida glabrata*; and therefore, should not be used as empiric therapy for invasive candida infections in hemodynamically unstable patients. It has good CNS penetration and may be used in stable patients with endophthalmitis and meningitis due to sensitive *Candida* species. It is effective in the primary treatment of coccidiomycosis and as maintenance therapy for disseminated cryptococcal infections. It is ineffective against the molds and is not reliable against *Histoplasma* or *Blastomyces*. Voriconazole is the first-line agent against invasive *Aspergillus fumigatus* infections and has been found to be superior to traditional amphotericin B against such infections.¹⁹ It is also active against *Fusarium* and *Scedosporium* species as well as some fluconazole resistant *Candida* species. It has no activity in mucormycosis. The intravenous form should be used with caution in patients with renal insufficiency due to potential accumulation of cyclodextrin, a vehicle used in the formulation. Posaconazole has expanded the spectrum of the triazole agents to include the Zygomycetes while maintaining activity against yeasts and molds covered by voriconazole. It may show activity against *Candida* species resistant to fluconazole and *Aspergillus* species resistant to amphotericin B and voriconazole. Posaconazole has shown promising results as a salvage therapy for the treatment of refractory fungal CNS, lung, oropharyngeal, and esophageal infections. Posaconazole is currently only available in the oral form. Absorption is improved when taken with high fat meals. Azoles are potent cytochrome P-450 enzyme inhibitors, leading to interactions with many drugs including cyclosporine, phenytoin, tacrolimus, and warfarin. The most common adverse effects of the azoles are gastrointestinal upset and reversible transaminitis. Voriconazole has been noted to cause transient visual disturbances.

Echinocandins (Caspofungin, Micafungin, and Anidulafungin)

The echinocandins act by inhibiting β -1,3 glucan synthase, thus disrupting cell wall synthesis.

These agents are rapidly fungicidal against most *Candida* species and fungistatic against *Aspergillus* species. They are first-line agents for treatment of invasive *Candida* infections in critically ill patients, neutropenic patients, and those with prior azole exposure. At present, all 3 echinocandins should be viewed as equally effective for candidemia. In clinical trials, they have shown superior microbiologic and clinical cure rates to fluconazole when treating candidemia, including that caused by fluconazole-sensitive *Candida albicans*.²⁰ In addition, they may be used in combination with amphotericin B or voriconazole for treatment of invasive aspergillosis. They have no activity against mucormycosis and cryptococcal species. They are generally well tolerated with the most commonly reported side effects being headaches, chills, elevated liver enzymes, and phlebitis at the infusion site.

Antivirals

Nucleoside Analogues (Acyclovir, Valacyclovir, Ganciclovir, and Valganciclovir)

These drugs require phosphorylation in virally infected cells to become active. They then become competitive substrates for the viral DNA polymerase, causing chain termination. Acyclovir is the drug of choice for all forms of HSV-1 disease including encephalitis, pneumonia, and hepatitis as well as for genital disease due to HSV-2. It is also used for pneumonia or disseminated disease due to VZV. It is not effective for EBV or CMV disease. Valacyclovir is a prodrug which has enhanced oral bioavailability; it is converted to acyclovir after first-pass metabolism. Resistance to acyclovir most commonly develops from mutations in viral thymidine kinase. Ganciclovir is the mainstay of treatment and prophylaxis of CMV retinitis, pneumonitis, and gastrointestinal infections in immune-compromised (HIV, solid organ and bone marrow transplant) patients. Ganciclovir has activity against HSV and VZV, but its toxicity profile precludes its use in these infections. Resistance to ganciclovir results from either reduced phosphorylation because of mutations in viral phosphotransferase gene or secondary to mutations in the gene encoding viral DNA polymerases. Valganciclovir, a prodrug, is converted to ganciclovir providing a potent oral alternative to intravenous

ganciclovir. The adverse effects of the nucleoside analogues are primarily seen when the drugs are given in high doses intravenously. Nephrotoxicity can occur with either drug. Acyclovir can precipitate in renal tubules; this can be prevented with adequate volume administration and slow infusion rates. Reversible myelosuppression (neutropenia, thrombocytopenia) is the most notable adverse effect of ganciclovir, occurring in 25% to 30% of recipients. Both drugs can cause CNS toxicity including confusion, seizures, extrapyramidal signs, and autonomic instability.

Pyrophosphate Analogues (Foscarnet)

Foscarnet acts by inhibiting DNA and RNA polymerases. It is active against CMV, HSV, and VZV. Foscarnet is the drug of choice for the treatment of CMV infections in individuals unable to tolerate ganciclovir, for patients with acyclovir-resistant HSV and VZV infection, and for those with ganciclovir-resistant CMV infections. Nephrotoxicity is a common adverse effect of foscarnet. Bone marrow suppression and transaminitis may also occur.

Neuraminidase Inhibitors (Oseltamivir and Zanamivir)

Oseltamivir and zanamivir are active against influenza A and influenza B. They are indicated for suspected or confirmed influenza infection in all critically ill patients. Oseltamivir is only available in oral formulation. Zanamivir can be delivered as an inhalational drug but this form cannot be given to patients on mechanical ventilation. An intravenous formulation of zanamivir exists, but currently can only be obtained from the manufacturer as compassionate release. The prompt receipt of these medications has been associated with improved outcomes in patients with pandemic H1N1 influenza. They are usually well tolerated, with the most common side effects being headache, dizziness, and vertigo. Inhaled zanamivir can cause bronchospasm and is contraindicated in patients with asthma and chronic obstructive pulmonary disease.

Endocrine Dysfunction Leading to Critical Illness

Michael A. Via, MD and Jeffrey I. Mechanick, MD

KEY POINTS

- 1 The immune-neuroendocrine response of critical illness (CI) is marked by hypercatabolism and diminished hypothalamic-pituitary-end-organ function.
- 2 Despite low circulating growth hormone (GH) levels in CI, the administration of exogenous GH is detrimental.
- 3 Central adrenal insufficiency typically results from overly rapid tapering of corticosteroid dosing or increased stress in a patient who was recently tapered off of corticosteroids.
- 4 CI or relative adrenal insufficiency, though real and relevant, is still the subject of great interest among intensivists and changes in definitions and management are likely to change in the near future.
- 5 Diabetic ketoacidosis typically occurs in patients with type 1 diabetes that are newly diagnosed, acutely ill, or resulting from missed scheduled insulin doses.

INTRODUCTION

The endocrine system of extracellular hormone signaling maintains homeostasis via regulation of metabolic pathways and cellular function in multicellular organisms, including humans. During critical illness (CI), the extreme systemic inflammatory response disrupts normal physiology and alters hormone signaling. The immune-neuroendocrine response of CI is marked by hypercatabolism and diminished hypothalamic-pituitary-end-organ function. In some cases, disorders of the endocrine system directly lead to CI. This chapter reviews the endocrine and metabolic physiology and sequelae of CI as well as specific conditions of the endocrine system that can lead to CI.

PITUITARY FUNCTION AND CRITICAL ILLNESS

The pituitary gland, or hypophysis, is located within the sella turcica, inferior to the optic chiasm and is connected to the hypothalamus via the infundibulum. The pituitary is divided functionally and anatomically into anterior and posterior sections. Although much of its function is controlled by the hypothalamus, the pituitary is considered the “master gland” for its role in regulating many of the other endocrine glands.

The anterior pituitary secretes 6 major peptide hormones: growth hormone (GH), prolactin (PRL), thyroid stimulating hormone (TSH),

adrenocorticotrophic hormone (ACTH), luteinizing hormone (LH), and follicle stimulating hormone (FSH). The secretion of each of these hormones is pulsatile and follows a circadian rhythm. PRL synthesis is primarily regulated by inhibitory dopaminergic neurons of the hypothalamus. The other peptide hormones of the pituitary are synthesized primarily in response to stimulatory hypothalamic hormones.

Hypothalamic and anterior pituitary function are greatly reduced in CI as a result of high levels of circulating inflammatory cytokines (Table 44–1).¹ In early CI, circulating GH, LH, and FSH levels diminish to negligible levels. TSH production initially rises sharply, but within 6 to 18 hours of CI, TSH secretion is also impaired as part of the nonthyroidal illness phenomenon. ACTH levels also initially increase as part of a generalized stress response of acute CI, but typically decline to below normal levels on day 3 of CI.² Cortisol levels generally remain elevated, even as ACTH levels decline after day 3, suggesting an independent mechanism governing the release of cortisol as patient progress into the prolonged phase of CI.²⁻⁴
